Figure 40-24. Technique of dorsal graft onlay popularized by Barbagli. A, The corpus spongiosum is detached from the triangular ligament and corpora cavernosa. B, A dorsal urethrostomy is performed. The graft is spread fixed to the corpora cavernosa. Note the pie-crusting incision. C, The edges of the stricturotomy are sutured to the graft and to the corpora cavernosa.

Figure 40-25. Technique of augmented anastomosis with graft onlay. A, The corpus spongiosum is detached from the triangular ligament and the corpora cavernosa. The area of spongiofibrosis is identified and marked, and the area of the narrowest caliber stricture is excised. The urethral ends are spatulated on the dorsum. B, A two-layer floor strip anastomosis is performed, and the graft is spread fixed to the corpora cavernosa. Note the pie-crusting incisions and the mattress sutures. C, The edges of the stricturotomy are sutured to the graft and to the corpora cavernosa.

anastomotic procedure) (Fig. 40-25). For proximal strictures, the vessel-sparing technique of augmented anastomosis depends on the surgeon's ability to excise the scarred epithelium and underlying corpus spongiosum tissue without the need to divide the corpus spongiosum completely.

Another option is the two-staged application of a mesh split-thickness skin graft, buccal mucosal graft, or posterior auricular

full-thickness skin graft. In the first stage of the staged graft procedure, a medium-thickness split-thickness skin graft, a buccal mucosal graft, or a Wolfe graft is placed over the dartos fascia. If the graft is placed immediately onto the tunica albuginea or corpora cavernosa, the inability to mobilize the graft makes second-stage tubularization difficult. However, there is an advantage to having at least a midline strip of the graft adherent to the corpora

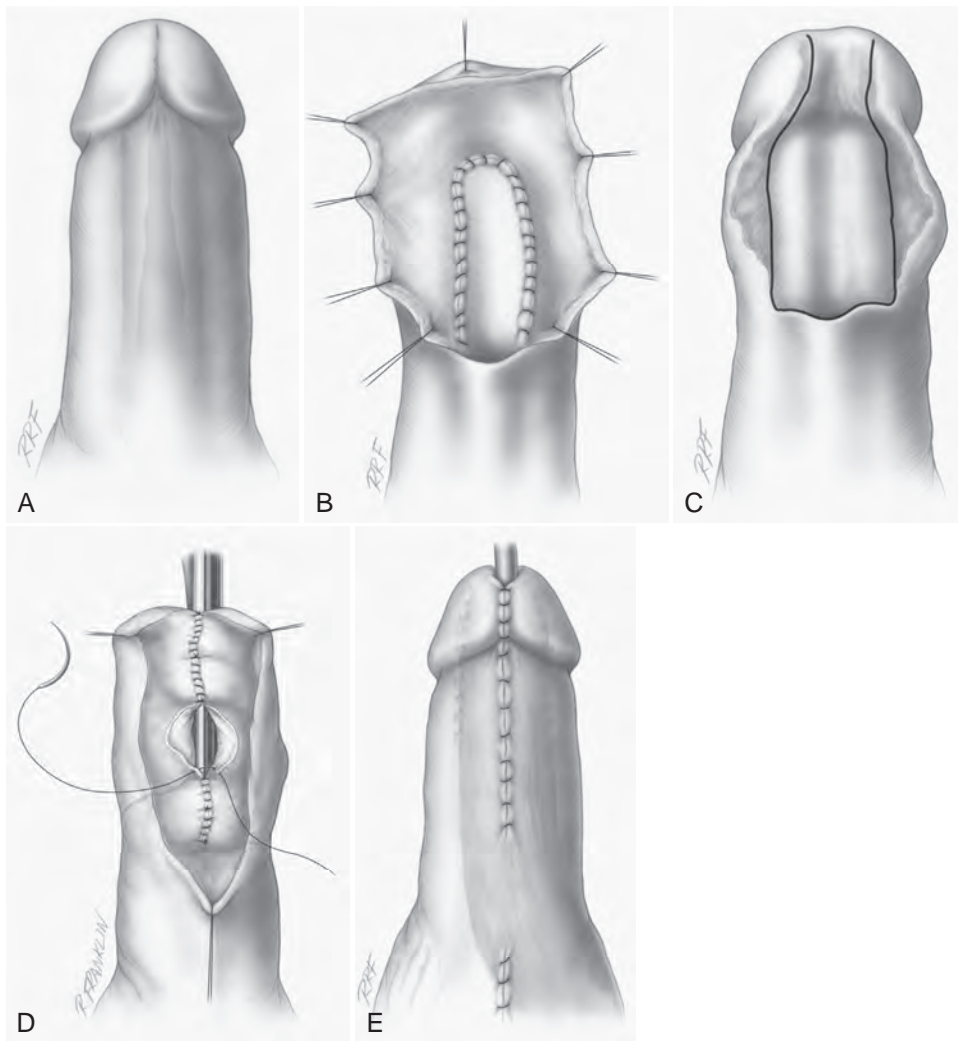

Figure 40-26. Staged reconstruction of a distal anterior urethral stricture. **A**, The appearance of the penis with the urethra (shaded area shows the location of a tight stenosis of the fossa navicularis that extends into the distal pendulous urethra). **B**, The distal narrow stricture of the fossa navicularis has been excised, and stricturotomy into the normal urethra proximal to the excised tissue has been performed. A buccal graft has been applied to the defect, but the bolster dressing has not yet been applied. **C**, After 6 months, the graft is mature. The illustration shows a Tiersch tube ready for closure. **D**, The Tiersch tube is closed with a watertight suture line. The distal urethra is usually calibrated to create a urethral lumen of approximately 28 Fr. **E**, Glans reconstruction and closure of the distal shaft has been performed (shaded area shows the tunica dartos flap that carries a parietal tunica vaginalis island). The flap is mobilized in this case from left hemiscrotum and transposed to cover the entire area of the urethral reconstruction.

cavernosa. At a later date, second-stage surgery is performed to tubularize the graft. Although Schreiter and Noll (1989), who first described the procedure of mesh split-thickness skin graft, often proceeded to the second stage within 3 to 4 months, we wait 12 months between the first-stage and second-stage surgeries if a split-thickness skin graft is used. This procedure has been found to be useful for select cases in the United States and Europe. In the United States, its use has mostly been confined to the most difficult cases, with single-stage reconstruction still applied to most cases. As already mentioned, staged graft techniques have been used effectively in complicated patients with hypospadias. Staged buccal graft operations have been successful in patients with LS with mid-term follow-up. In addition, in complicated patients with hypospadias, staged buccal grafts and posterior auricular skin grafts have been successfully employed (Fig. 40-26).

Numerous applications of genital skin islands, mobilized on either the dartos fascia of the penis or the tunica dartos of the scrotum, have been proposed for the repair of urethral stricture disease. In the past, these “flap operations” were considered separate procedures. We suggest that all these procedures are different applications of a single concept, as proposed by the microinjection studies of Quartey (1983). Skin islands can be viewed as passengers on fascial flaps, and the design of flaps for urethral reconstruction can be paralleled to the design of flaps for reconstruction in general.

There are three important considerations for the use of flaps in urethral reconstruction: the nature of the flap tissue, the vasculature of the flap, and the mechanics of flap transfer. The skin must be nonhirsute for urethral reconstruction. In addition, for

donor site consideration, it is most convenient to use the areas of redundant nonhirsute genital skin.

If the redundancy is dorsal, the skin island can be oriented transversely and mobilized on the dorsal dartos fascia after the techniques described by Duckett and Standoli in 1984 (Fig. 40-27) (Duckett, 1986; El-Kassaby et al, 1986; Duckett, 1992; Duckett et al, 1993). If there is redundancy of the ventral skin, the skin island can be mobilized as a ventral longitudinal island. These islands can be either vigorously mobilized on a ventrolaterally oriented dartos fascial flap for transposition to the perineum or less vigorously mobilized and transposed and inverted into a pendulous urethral stricture defect (Fig. 40-28) (Orandi, 1972). Ventral islands can be oriented transversely (Fig. 40-29) and longitudinally. Longer skin islands can be mobilized by orienting the island ventrally and transversely at the distal extent. This “hockey stick” orientation allows islands 7 to 9 cm (Fig. 40-30). For distal strictures of the anterior urethra, including the fossa and meatus and the pendulous urethra, the islands can be advanced to reconstruct to the level of the meatus by either developing glans wings or elevating the ventral glans.

Where there is general redundancy to the penile skin, the islands can be oriented circumferentially. These “circular skin islands” are mobilized on the entire penile dartos fascia, and the mechanics of transposition suggest that they are most efficient when they are ventrally based, with the pedicle split dorsally. In some cases, circular skin islands 15 cm can be obtained (El-Kassaby et al, 1986; McAninch, 1993; Miller and McAninch, 1993). The so-called Q flap circular island design can provide even longer islands, sometimes necessary for complex long-length anterior urethral reconstruction (Morey et al, 2000).

Figure 40-27. A dorsal transverse island of penile skin applied to a stricture of the urethra. The flap has been elevated on the dartos fascia, and a lateral incision into the urethra has been made. The flap is secured in place (*right*). (From Jordan GH. Management of anterior urethral stricture disease. In: Webster GD, editor. Problems in urology. Philadelphia: Lippincott; 1987. p. 217.)

It is often beneficial to combine the excision of the stricture with a skin island onlay (Fig. 40-31) or a graft onlay in an augmented anastomosis (see Fig. 40-25). We have found that segments of very narrow caliber (nearly or totally obliterating) are difficult. These segments can often be completely excised; a roof or floor strip anastomosis of the urethra is performed, and the remaining urethrotomy defect is filled with either a graft or a skin island onlay. In some patients, there are relatively large nonhirsute areas of the scrotal skin that can be elevated on the tunica dartos of the scrotum. This flap has been maligned in the literature in the past. However, we and others have extensive experience with these flaps and, in select cases, have had very good results. The fascial flap must be based laterally, and so oriented, these flaps have been shown to be extremely reliable. Because the tunica dartos has a significant muscle component, the skin island must be carefully tailored. If these skin islands are correctly tailored at the outset, they are not attended with diverticular development as some have believed they were in the past. Scrotal skin islands are not our first choice; however, for difficult cases, they remain a reasonable option.

These procedures using skin islands oriented on the penile dartos fascia have also been useful for reconstruction of the fossa navicularis (Cohney, 1963; Blandy and Tresidder, 1967; Brannen, 1976; De Sy, 1984; Jordan, 1987; Armenakas et al, 1998). In the past, meatal strictures and strictures of the fossa navicularis were managed with repeated dilations or sequential meatotomies. Because these meatotomies were seldom successful in the long-term, techniques were developed that allowed the spatulation of random penile skin flaps into the meatotomy defects. These procedures functionally improved the results; however, the cosmetic appearance of the penis was suboptimal. With the use of skin islands elevated on the dartos fascia, excellent functional and cosmetic results became the norm. The design of these islands must take into consideration the location of hair on the shaft of the penis and the mechanics of flap transfer (i.e., transposition vs. advancement) (Figs. 40-32 and 40-33). In addition, full-thickness skin has been used to reconstruct the fossa navicularis, but when they can be avoided, skin grafts are not considered appropriate for reconstruction in cases of LS. As already mentioned, there is question about the use of skin islands in general in patients with LS.

The literature is clear that onlay procedures (graft or flap) are associated with a higher success rate than tubularized grafts or tubularized skin islands (Hendren and Crooks, 1980). Tubularized grafts and skin islands should be avoided, if possible. When

Figure 40-28. Penile longitudinal skin island. The incisions to be made to mobilize the flap are demonstrated in the *inset*. The heavy line is the primary incision made full thickness through the dartos fascia and superficial Buck fascia lateral to the corpus spongiosum. A, Dissection elevates the dartos fascial flap well past the corpus spongiosum in the midline. B, A lateral urethrostomy placed to face the flap has opened the entire length of the stricture. C, The skin paddle of the flap has been developed by making the incision outlined by the dotted line (*inset*) and undermining the skin lateral to it. The medial edge of the flap has been fixed to the edge of the stricturotomy. D, The flap is inverted into the defect. E, A watertight subepithelial suture line has been completed with a running absorbable monofilament suture. The skin will be closed with subcutaneous sutures and interrupted cutaneous sutures. (From Jordan GH. Management of anterior urethral stricture disease. In: Webster GD, editor. Problems in urology. Philadelphia: Lippincott; 1987. p. 214.)

tubularized segments cannot be avoided, the length of these segments can be limited by combining aggressive mobilization and excision. Without question, tubularized flaps provide better results than tubularized grafts. Where extremely long segments of the anterior urethra require reconstruction, a flap can be used distally and augmented by graft onlay proximally (Wessells et al, 1997). Where tubed reconstruction is required, in a small series with only short follow-up, the combination of a graft spread fixed to reestablish the "urethral plate" with flap onlay seems perhaps to

Figure 40-29. A ventral transverse skin island is elevated on the penile dartos fascia, inverted to the area of the perineum where flap onlay is accomplished. A, The skin island is elevated on the dartos fascia. B, The appearance of the flap transposed to the area of the perineum for onlay in a proximal bulbous urethral stricture.

be better than tubed flap reconstruction, even when it is employed in the onlay-tube-onlay configuration (Morey, 2001).

More recently, Kulkarni and colleagues (2012) published their approach to a single-stage panurethral reconstruction. Through a perineal incision and invaginating the penis, they described using a dorsal graft from the proximal bulbar urethra to the meatus. The mean stricture length was 14 cm, and mean follow-up was 59 months. The overall success rate was 83.7%; for primary repairs, the success rate was 86.5% compared with 61.5% in patients who failed a previous urethroplasty. Most of the recurrences the authors described were proximal.

A flap procedure that can be used as an alternative to split-thickness skin grafts when nonhirsute skin is unavailable is the epilated midline genital skin island. Similar to a split-thickness skin graft, this procedure must be viewed as a staged procedure, with the epilations being the initial stage or stages. Epilation can be accomplished with either a narrow-gauge needle and monopolar cautery or epilation needles and machines. The interval between the epilations must be 6 to 8 weeks, and urethral reconstruction cannot be accomplished until 10 to 12 weeks after the last epilation. The actual stricture repair involves elevation of the midline skin island, based on the dartos fascia of the penis and the tunica dartos of the scrotum. As with nonhirsute scrotal skin islands in general, the importance of meticulous tailoring of the scrotal portion of the island cannot be overemphasized.

Mundy (1994) analyzed a large series of urethral reconstructions. His data showed that when follow-up is limited to 1 year, the success rate with tissue transfer clusters is about 95%. However, with longer follow-up, there is deterioration over time. With excision and primary anastomosis, the success seen at 1 year seems to be more durable and does not appear to deteriorate at the same rate with time. We have reported our long-term data for excision and primary anastomosis with anterior urethral stenosis in 220 patients with a mean follow-up of 44 months; three recurrences were noted, two within the first 6 months and a third at 4 years. The rate of postoperative erectile dysfunction is 2%, with patients with severe straddle injuries being at

increased risk. In a meta-analysis of graft onlay procedures compared with flap procedures, Wessells and McAninch (1998) showed equivalent results for graft operations and flap procedures, and graft onlay procedures are technically far easier to perform. There are some cases where flap reconstruction would be expected to provide superior results (i.e., radiation strictures, patients with multiple operations, pendulous strictures). However, with the increased knowledge gained by the enthusiastic application of graft reconstruction, a paradigm for anterior reconstruction has been redefined. Although grafts have been used successfully for all segments of the anterior urethra, many authors think that, all other variables being equivalent, flaps are best suited for distal reconstruction, and grafts are best for proximal reconstruction (Greenwell et al, 1999).

Postoperative erectile dysfunction is an important issue. Our rates for anterior urethral anastomotic reconstruction were quoted earlier. In an analysis by Coursey and colleagues (2001), 200 patients who underwent urethroplasty were studied. Overall, the rate of erectile dysfunction after urethroplasty was approximately equal to the rate after circumcision. Longer-segment reconstructions were associated with a higher risk of postoperative erectile dysfunction, although the patient's erectile function improved over time in many cases.

Special mention is needed regarding reconstruction for strictures associated with LS. With the advent of flap techniques, many centers embraced these techniques for these strictures. However, analysis of results from patients with LS treated at several large centers showed a very high recurrence rate. Consequently, these centers adjusted the techniques by applying staged graft techniques (see Fig. 40-26). Staged graft techniques using skin grafts also had a very high recurrence rate in many analyses. Theoretically, because LS is a skin condition, the use of skin as a flap, single-stage graft, or staged graft does not preclude involvement of the skin with the inflammatory process (Lee and Phillips, 1994; Akporiaye et al, 1997). Surgeons at numerous centers believe that staged oral graft techniques should be employed for reconstruction of strictures associated with LS. Short-term follow-up results suggest better success

Figure 40-30. Ventral skin island for long bulbous stricture. The skin paddle of the flap is developed on the ventral midline of the penis and can be extended around the penile shaft at its distal end. A, The paddle of the flap has been incised, and its pedicle has been elevated. This pedicle includes Buck fascia and dartos fascia, denuding the tunica of the corpus spongiosum and the corpora cavernosa. The pedicle (the dartos fascia bilaterally) is based on the superficial external pudendal vessels and the internal pudendal vessels in the scrotum. Development of this pedicle allows the flap to be moved to any area of the urethra. B, The flap has been passed through a tunnel beneath the scrotum developed by dissection along the corpus spongiosum. A laterally placed urethrostomy has opened the urethral stricture. C, The deep edge of the flap is secured by the suture techniques previously described. D, Anastomosis of the flap has been completed. The pedicle can be seen extending beneath the scrotum. (From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary surgery, part III. AUA Update Series 1988;7:lesson 11.)

with this approach. Long-term follow-up results are unavailable. In a review of our experience in patients with a fossa navicularis stricture and LS, we noted a 50% recurrence in the stricture with a ventral transverse skin island (Virasoro et al, 2007).

PELVIC FRACTURE URETHRAL INJURIES

PFUIs are the result of blunt pelvic trauma and accompany about 10% of pelvic fracture injuries. Although total disruption of the urethra is possible with a straddle injury, these injuries most

commonly involve only the bulbous urethra. However, the ensuing spongiofibrosis can be associated with complete obliteration of the urethra. Distraction injuries are unique to the membranous urethra. Pelvic fracture distraction injuries of the membranous urethra have been compared with plucking an apple (prostate) off its stem (the membranous urethra). This analogy implies that the injury most frequently occurs at the apex of the prostate. However, experience shows that this is not the case, and the most frequent point of distraction is at the departure of the bulbous urethra from the membranous urethra (Andrich and Mundy, 2001; Mouraviev and Santucci, 2005). The distraction can

Figure 40-31. Reconstruction in a patient with a long anterior urethral stricture with a relatively short narrow-caliber section (technique of augmented anastomosis with circular skin island). **A**, A circular skin island is elevated on the dartos fascia. The patient is positioned flat on the table. **B**, The skin island onlay is begun, the rest of the flap is placed into the perineal dissection, and the penis is closed; the patient is then repositioned in the lithotomy position. **C**, The flap is retrieved through the perineal dissection. The narrow-caliber section is excised, and the urethra is spatulated on the dorsum. **D**, The onlay is completed, and the floor strip anastomosis is closed. **E**, Schematic of the surgery. (From Stack RS, Schlossberg SM, Jordan GH. Reconstruction of anterior urethral strictures by the technique of excision and primary anastomosis. *Atlas Urol Clin North Am* 1997;5:11–21.)

involve all or any portion of the membranous urethra between the departure of the bulbous urethra and the apex of the prostate. In postpubescent male patients, the injury seldom involves the prostatic urethra. In prepubescent male patients, in whom the prostatic urethra is more fragile, the injury can extend into that area.

Total distraction of the entire circumference of the urethra appears not to occur with many injuries. Instead, a strip of epithelium is left intact. In these patients, the placement of an aligning catheter may allow the urethra to heal virtually unscarred or with an easily managed stenosis. Because of flexible

endoscopy equipment, the placement of an aligning catheter is straightforward. If distraction is complete, the catheter serves to align the obliterated urethral ends, and reconstruction is facilitated. Because of the ready availability of flexible cystoscopes, some centers acutely evaluate these injuries only with endoscopy. Clinicians who are enthusiastic for this approach believe that not only can the injury be completely evaluated, but also the entire process, including the placement of an aligning catheter, is expedited (Kielbaso et al, 2001). Aligning catheters are just what the name implies—a guide, not a mechanism for placing traction on the bladder and

KEY POINTS: TREATMENT OF URETHRAL STRICTURE

- In the treatment of urethral stricture disease, the patient and the physician must have a good understanding of the goals of treatment before the treatment choice is made.
- Urethral dilation is the oldest and simplest treatment of urethral stricture disease. However, the goal of dilation is to stretch the scar atraumatically. Dilation is seldom used curatively.
- Internal urethrotomy refers to any procedure that opens the stricture by incising it transurethrally. The factors that contribute to success of internal urethrotomy have been defined as follows: internal urethrotomy should be reserved for strictures of the bulbous urethra; the stricture should be less than 1.5 cm in length; and the stricture should not be associated with dense deep spongiofibrosis. Many studies have shown that repeated dilation and internal urethrotomies diminish the success rate of eventual open urethral reconstruction.
- Numerous lasers have been used for anterior urethral strictures. To date, the results of laser urethrotomy are mixed.
- Excision with primary anastomosis has proved to be the gold standard for repair of anterior urethral strictures. Previously, excision with primary anastomosis was thought to be a relatively limited procedure and applicable only for strictures less than 1.5 to 2 cm. However, with better understanding of the anatomy, longer strictures have been successfully addressed with excision and primary anastomosis.
- Some strictures require tissue transfer, and grafts and flaps have been successfully employed. A meta-analysis by [Wessells and McAninch](#) (1998) showed that the results of graft reconstruction and flap reconstruction are equivalent. The complexity of flap procedures is greater than that of graft procedures. The concept of augmented anastomosis can be used with graft and flap onlay and is thought to provide better results than just pure onlay in many cases. When flaps are employed for urethral reconstruction, conceptually all become one operation with multidimensional application.

prostate. Aligning catheters also seem to act as a drain as the pelvic hematoma liquefies, and perhaps the presence of the catheter may allow more rapid and complete resolution of the process ([Cohen et al, 1991](#); [Herschorn et al, 1992](#); [Rehman et al, 1998](#); [Mouraviev et al, 2005](#)). Close follow-up after a voiding trial is essential because many of these patients experience stricture formation after removal of the aligning catheter and require definitive repair ([Leddy et al, 2012](#)).

Evaluation

As with the repair of any stricture or stenosis, it is important to define the precise anatomy of the pelvic fracture injury before treatment is undertaken ([McCallum and Colapinto, 1979a, 1979b](#)); this includes the depth, density, length, and location. In pelvic fracture urethral distraction defects, the depth and density of fibrosis are predictable. Although the location of the distraction injury has been shown to be an important factor in continence after reconstruction, this information should be a factor only in counseling of patients before the reconstruction and not in the treatment approach. The length of the defect is an important consideration and must be determined as precisely as possible.

Contrast studies are a first-line tool for the evaluation of PFUI. A cystogram outlines the bladder and provides information about rostral displacement of the proximal urethra. A lack of contrast material in the posterior urethra gives some information, albeit inconclusive, about the integrity of the bladder neck.

When the patient is successful in relaxing to void and the cystogram outlines the posterior urethra, a simultaneous retrograde urethrogram outlines the length of the injury defect.

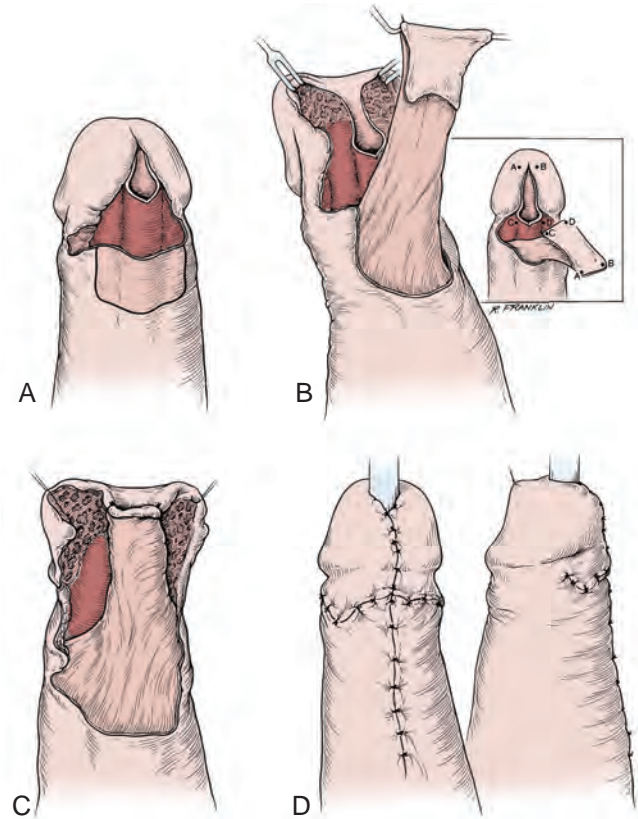

Figure 40-32. Technique of reconstruction of the fossa navicularis after Jordan. **A**, The ventral corpus spongiosum is exposed, and the urethra is opened ventrally through the area of stenosis. A transverse ventral skin island is outlined on the distal penile skin. **B**, The skin island is elevated on the ventral dartos fascia. **C**, The skin island is transposed and inverted into the meatotomy defect (*inset, B*). **D**, Appearance of the penis closed after the procedure. (**A** to **C**, From Jordan GH. Reconstruction of the fossa navicularis. *J Urol* 1987;138:1210; **D**, from Jordan GH. Reconstruction of the meatus-fossa navicularis using flap techniques. In: Schreiter F, editor. *Plastic-reconstructive surgery in urology*. Stuttgart: Georg Thieme; 1999. p. 338–44.)

Figure 40-33. Technique after De Sy, in which a ventral longitudinal skin island is advanced into the meatotomy defect. The skin island is developed by de-epithelialization of a portion of the longitudinal flap. (From Jordan GH. Management of anterior urethral stricture disease. *Probl Urol* 1987;1:199–225.)

However, this situation is the exception rather than the rule, and retrograde urethrography is most useful for determining whether the anterior urethra is normal. If the anterior urethra is normal, it has been our experience and the experience of others that a successful anastomotic repair is ensured. A primary anastomosis has

been shown to be possible even with some involvement of the anterior urethra. Even in cases of prior failed posterior urethral reconstruction, primary anastomotic repair is often feasible, although the failure rate is slightly higher in these cases (Chapple and Pang, 1999; Flynn et al, 2003; Koraitim, 2003; Shenfeld et al, 2004). **Primary anastomosis is unquestionably the goal in all patients until it is proved impossible to perform.**

When the proximal urethra is not visualized on a simultaneous cystogram with urethrogram, endoscopy through the suprapubic tract in combination with retrograde urethrography can be used to outline the defect. After the endoscopic appearance of the bladder neck is assessed, the flexible endoscope can be advanced through the bladder neck and into the posterior urethra to the level of the obstruction. **The appearance of the bladder neck on contrast studies or on antegrade endoscopy does not accurately predict the ultimate function of the bladder neck after urethral reconstruction (Iselin and Webster, 1999).** A simultaneous retrograde urethrogram outlines the anterior urethra, with the space not visualized representing the injury defect.

Some authors have advocated MRI for the evaluation of patients with PFUIs. We have had little experience with MRI for that purpose; however, we have found the information obtained on the few studies that we have done to be useful. In these cases, there was the question of bone interposition into the injury defect, and MRI outlined this. We evaluated a case in which the prostatic urethra appeared obliterated. On MRI, one could easily see that the prostate was not only distracted from the membranous urethra but also distracted from the bladder. This information was essential to planning of subsequent reconstruction in this case. It would seem intuitively obvious that knowing the length of distraction would be helpful in determining the precise approach and steps necessary for reconstruction. However, the literature is unclear on this matter (Andrich et al, 2003; Koraitim, 2004), and it is our experience that the surgeon must be prepared to exercise all options of reconstruction in virtually all such cases (McCallum and Colapinto, 1979a, 1979b).

Repair

The timetable for the reconstruction of PFUIs is determined by the type and extent of associated injuries. If possible, it is desirable to proceed within 4 to 6 months after trauma. However, orthopedic injuries of the lower extremities often necessitate a delay in proceeding with urethral reconstruction (Mundy, 1991; Follis et al, 1992; Brandes and Borrelli, 2001).

In most cases, PFUIs are not long, and the resultant obliteration is amenable to a technically straightforward mobilization of the corpus spongiosum with a primary anastomotic technique. The classic reconstruction consists of a spatulated anastomosis of the proximal anterior urethra to the apical prostatic urethra. However, experience has demonstrated that anastomosis of the proximal anterior urethra to any segment of the posterior urethra (apical, prostatic, or below) can be successfully accomplished by a widely spatulated anastomosis in which optimal epithelial apposition is achieved. About 10% of PFUIs are associated with more complex injuries and can be associated with fistulae (most commonly urethral rectal fistulae). Reconstruction of these injuries is technically more demanding.

Several series support the concept that the bulk of PFUIs, even the most difficult cases, can be managed by the perineal approach (Webster et al, 1983; Koraitim, 1985; Webster and Sihelnik, 1985; Webster et al, 1990; Morey et al, 1996; Koraitim, 1997; Flynn et al, 2003). A transpubic or an abdominal-perineal approach, as pioneered by Waterhouse and colleagues (1973), in our experience, is unnecessary for the reconstruction of distraction injuries. In addition, pubectomy can be associated with long-term sequelae, including shortening of the penis, destabilization of erection, and destabilization of the pelvis, resulting in a chronic pain syndrome with exercise. However, some surgeons continue to rely heavily on the transpubic approach (Koraitim, 1997; Das et al, 2004).

Alternatively, the above-and-below approach has merit when concomitant surgery is planned in the region of the bladder neck. We have found and Iselin and Webster (1999) reported that the competence of the bladder neck is difficult to assess accurately before the reestablishment of urethral continuity. In the past, great reliance was placed on whether the bladder neck was closed or open on cystography. However, contrast material may opacify the prostatic urethra when the bladder neck is more than adequately competent for continence. Similarly, confidence has been placed in the appearance of the bladder neck on endoscopic examination through the suprapubic tube. Again, even when an obvious scar is noted to involve the bladder neck, follow-up of these patients after urethral reconstruction establishes continuity of the urethra and finds many patients with more than adequate continence. Other patients are believed to have incontinence secondary to scar incarceration of the bladder neck, caused by the extensive fibrosis left behind by resolution of the hematoma. However, in our experience, this is an infrequent occurrence, and the appearance of the bladder neck by any modality available is not predictive of continence. It is currently our practice to reestablish the continuity of the urethra and, when there are concerns about continence, to forewarn the patient before the urethral reconstruction. If these patients find that they experience inadequate continence postoperatively, the problem is addressed in a subsequent procedure (Bhargava et al, 2004).

At the time of reconstruction, before the patient is placed in the lithotomy position, endoscopy is performed through the meatus and again through the suprapubic tube sinus. Endoscopy on the table is designed to ensure that there is no concomitant vesicolithiasis. The endoscopy is performed with a rigid endoscope, which is manipulated through the suprapubic tube sinus and the bladder neck and positioned against the area of total obliteration. On gentle manipulation of the endoscope, if the impulse of the endoscope tip is felt on the patient's perineum, the impulse is palpable when the perineum is opened, and an instrument is manipulated through the bladder neck during reconstruction. If the impulse is not palpable perineally at this time, it may not be palpable during dissection. We create a temporary vesicostomy in these cases, which allows us to position an instrument reliably through the bladder neck because the vesicostomy allows the surgeon to identify the bladder neck palpably before instrumentation of the posterior urethra. This maneuver has eliminated the occurrence of false passages with use of a sound such as the Haygrove staff through the suprapubic site and has eliminated the occurrence of misanastomosis of the anterior urethra to sites other than the apical proximal urethra.

We prefer the use of the exaggerated lithotomy position for the perineal approach (Fig. 40-34). This position is safe and provides optimal exposure to the area of the membranous and apical prostatic urethra (Angermeier and Jordan, 1994). A custom Skytron table, modified to allow the exaggerated lithotomy position, and a Stille-Scandia table, designed to place patients in the lithotomy position, are our preferences. The legs are carefully positioned in Allen-style or Guardian-style stirrups. Care is taken to avoid pressure on the lateral aspects of the lower extremities and calf muscles. The patient's hips are elevated into position by raising the buttocks portion of the operating table. The boots are positioned to avoid stretch injuries of the common peroneal nerves (see Fig. 40-34).

After the patient is correctly positioned, the perineal approach to reconstruction begins with an incision and dissection anterior to the transverse perinei musculature (anterior perineal triangle). This is in contrast to the approach posterior to the transverse perinei musculature (posterior anal triangle), which is useful for perineal prostatectomy. We use a λ -shaped incision (Fig. 40-35) that is carried sharply down to the midline fusion of the ischiocavernosus musculature (see Fig. 40-35A), then beneath the scrotum, to expose the uninvested portion of the corpus spongiosum. We then place a self-retaining ring retractor.

The fusion of the ischiocavernosus musculature is divided, and the musculature is cleanly dissected from the corpus spongiosum and bulbospongiosum (see Fig. 40-35B to D). The corpus spongiosum is detached from the triangular ligament and corpora cavernosa (see Fig. 40-35E), the bulbospongiosum is detached from the

Figure 40-34. Patient placed in an exaggerated lithotomy position. The hips have been rotated into position by elevation of the buttocks portion of a specially modified table. The legs are suspended from boot-style stirrups with as little flexion of the hips and knees as allowed by the design of the stirrups. (From Angermeier KW, Jordan GH. Complications of the exaggerated lithotomy position: a review of 177 cases. *J Urol* 1994;151:866–8.)

perineal body, and the dissection is carried farther down to the infrapubic space. Posterior detachment of the bulbospongiosum is carried anteriorly, and the dissection is eventually carried through the area of fibrosis (see Fig. 40-35F).

In some cases, the proximal blood supply is encountered and must be controlled. We have found that these arteries are easily controlled with a sharp-tipped hemostat and monopolar cautery. Suture ligation should be avoided in the arteries to the bulbospongiosum because of their proximity to the nerves as they are coursing into the corpora cavernosa.

We divide the triangular ligament and vigorously develop the intracural space down to the pubis (Fig. 40-36). If the dorsal vein is encountered, it is ligated and divided. It is important to ensure that the arteries were not rolled into the intracural space if the tissues were dislocated during trauma. The penetration of the cavernosal arteries or the dorsal arteries, or both, into this space is commonly seen. If there is doubt about the nature of the vessels encountered, Doppler sonography should be performed. When the pubis is exposed, the periosteal elevator can be gently introduced onto the retropubic surface, releasing and allowing the descent of the tissues from beneath the pubis.

We introduce a Haygrove staff into the suprapubic sinus and through the bladder neck to the distal limits of the posterior urethra (see Fig. 40-35G and H). The impulse is palpated, and the fibrosis is resected until normal tissue is encountered. The tissue is submitted for histologic examination. The tip of the Haygrove staff is eventually concealed only by the normal urethral epithelium, at which point we open the epithelium and control it with either a skin hook or a stitch. We perform endoscopy to ensure that the urethrotomy is at the distal limits of the posterior urethra. If a tension-free anastomosis is thought to be impossible, we mobilize the corpus spongiosum beneath the scrotum from its attachment to the corpora cavernosa. Aggressive mobilization of the corpus spongiosum is the last maneuver undertaken because it is thought to have possible ill effects on the retrograde blood supply, which in a patient with pelvic fracture may be tenuous. Meticulous detachment of the investment of Buck fascia from the corpus spongiosum increases the compliance of the corpus and limits the need for aggressive mobilization.

It is important to try to avoid the creation of chordee during the repair of a distraction injury. To prevent chordee, the attachment cannot be carried beyond the area of the penoscrotal attachment. However, it is warranted in some cases to counsel patients preoperatively that they may have some chordee after aggressive mobilization that results in a primary anastomotic repair. Primary anastomotic repairs have success rates in the high 90% range. If a

technique of tissue transfer is needed, the long-term cure rates may eventually be only in the mid-80% range. Most of these patients are young. Successful, durable reconstruction is of paramount importance. If chordee results, it is most often mild and not disabling sexually; in our and other surgeons' minds, it is probably a fair trade for optimizing the urethral reconstruction. Development of the intracural space—mobilization of the corpus spongiosum, infrapubectomy, and, if needed, rerouting of the corpus spongiosum—shortens the course that the corpus spongiosum must traverse and allows reconstruction without attendant chordee.

The proximal urethrotomy is spatulated so that it accepts at least a 32-Fr bougie à boule, and 10 to 12 anastomotic sutures are placed and tagged to allow identification of their position in the proximal anastomosis. We have used a combination of 3-0 Monocryl and 3-0 polydioxanone sutures for this purpose. No special needles are required for the placement of these sutures. However, a Heaney needle driver and a Ravitch needle driver can be useful in difficult cases. After spatulation of the proximal urethrotomy and placement of the sutures, we spatulate the proximal portion of the anterior urethra. The spatulation is continued until the urethrotomy accepts a 30-Fr to 32-Fr bougie à boule, and the anastomotic sutures are placed in their respective locations. Before seating the anastomosis, we introduce a soft silicone (Silastic) ribbed urethral stenting catheter through the anastomosis under direct vision. The wound is copiously irrigated to reduce the clot around the area of the anastomosis, and the anastomosis is seated.

Next, we reattach the corpus spongiosum to the corpora cavernosa and the bulbospongiosum to the perineal body. We place a small suction drain deep to the closure of the ischiocavernosus musculature and Colles fascia and a second one superficial to that closure and beneath the subcutaneous closure.

In cases in which the proximal urethra is significantly distracted in a rostral direction, the surgeon must be prepared to perform infrapubectomy (Fig. 40-37) or corporeal rerouting, or both (Fig. 40-38). Performance of the infrapubectomy, along with the development of the intercrural space, allows exposure of the apical prostatic urethra. When the prostatic urethra remains rostrally displaced, the impulse of the sound or instrument placed through the cystostomy tract into the bladder neck is often not readily apparent. In these situations, it is comforting to be able to palpate the bladder neck and the properly placed sound before embarking on a dissection beneath the pubis. In addition, if the rostral distraction is significant, the path of the anterior urethra over the hilum of the penis into the infrapubectomy often does not allow a tension-free anastomosis, and the infrapubectomy can be continued beneath

one side of the corpora cavernosa, allowing rerouting of the corpus spongiosum (see Fig. 40-38).

Postoperative Management

We use a small soft silicone (Silastic) stenting catheter. Urine is diverted via the suprapubic cystostomy, and the urethral catheter is plugged and serves as a stent only. After the reconstruction, patients are initially kept at bed rest for 24 to 48 hours and then ambulated and discharged with the suprapubic catheter and stenting urethral catheter in place. Patients are discharged on a regimen of oxybutynin and a suppressive antibiotic only if the preoperative urine culture was positive. The drains are removed as drainage allows.

A voiding trial with contrast material is performed between 21 and 28 days postoperatively. Patients are directed to stop taking oxybutynin 24 hours before the voiding trial. In anastomoses that are technically straightforward, the trial is performed at 21 days, and

in cases with more rostral distraction of the proximal urethra, the trial is delayed for 3 to 5 days longer. The trial involves removing the urethral catheter, filling the patient's bladder with contrast material, and instructing him to void. We do not use pericatheter retrograde urethrography to evaluate patients who have undergone urethral reconstruction. The voiding film is examined to ensure that there is no extravasation and that the reanastomosis appears widely patent. A urine culture specimen is also obtained, and the suprapubic catheter is plugged. The patient is allowed to void through the urethra for 5 to 7 days, and the suprapubic catheter is then removed. Approximately 6 months postoperatively and again 1 year later, patients are evaluated with flexible endoscopy. At that time, we consider the reconstruction to be mature, and it should be widely patent. If no symptoms have reappeared, we refer further follow-up examinations to the referring urologist.

We have almost completely replaced postoperative retrograde studies with flexible endoscopy. We have not found flow studies

Figure 40-36. Division of the triangular ligament and development of the intracanal space. A, When the prostatic urethra is displaced, and the arc that the urethra must traverse needs to be shortened, that length can be shortened by incision of the triangular ligament. B, Incision and mobilization of the perichondrium and periosteum of the symphysis pubis to allow placement of retractors without trauma to the erectile bodies. Lateral displacement of the crura exposes the dorsal vein of the penis; after careful identification, the vein can be ligated and divided. C, Completion of the dissection affords additional exposure for resection of the fibrosis that surrounds the apex of the prostate and the proximal end of the disrupted urethra. (From Jordan GH. Reconstruction of the meatus-fossa navicularis using flap techniques. In: Schreiter F, editor. Plastic-reconstructive surgery in urology. Stuttgart: Georg Thieme; 1999. p. 338–44.)

Figure 40-35. Perineal repair of a membranous urethral stricture. A λ -shaped incision extends from the midline of the scrotum to the ischial tuberosities. A, Colles fascia has been opened to expose the midline fusion of the ischiocavernosus muscles and the tunica of the corpus spongiosum distal to the edge of the muscles. B, The scissors are introduced to develop the space between the muscle and the bulb of the urethra. C, An incision is made in the midline with the scissors, exposing the length of the bulb. D, The ischiocavernosus muscle is retracted to expose the full length of the bulb. E, The self-retaining retractor is placed to expose the inferior fascia of the genitourinary diaphragm. The bulb of the corpus spongiosum (bulbospongiosum) can be mobilized to gain access to the fibrosed area of the urethra. F, The fibrosed urethra is incised, freeing the bulb. G, The anterior urethra is opened to make an adequate lumen. H, The Haygrove staff has been passed through the suprapubic cystostomy. Resection of the fibrotic distraction defect has allowed it to pass into the perineum.

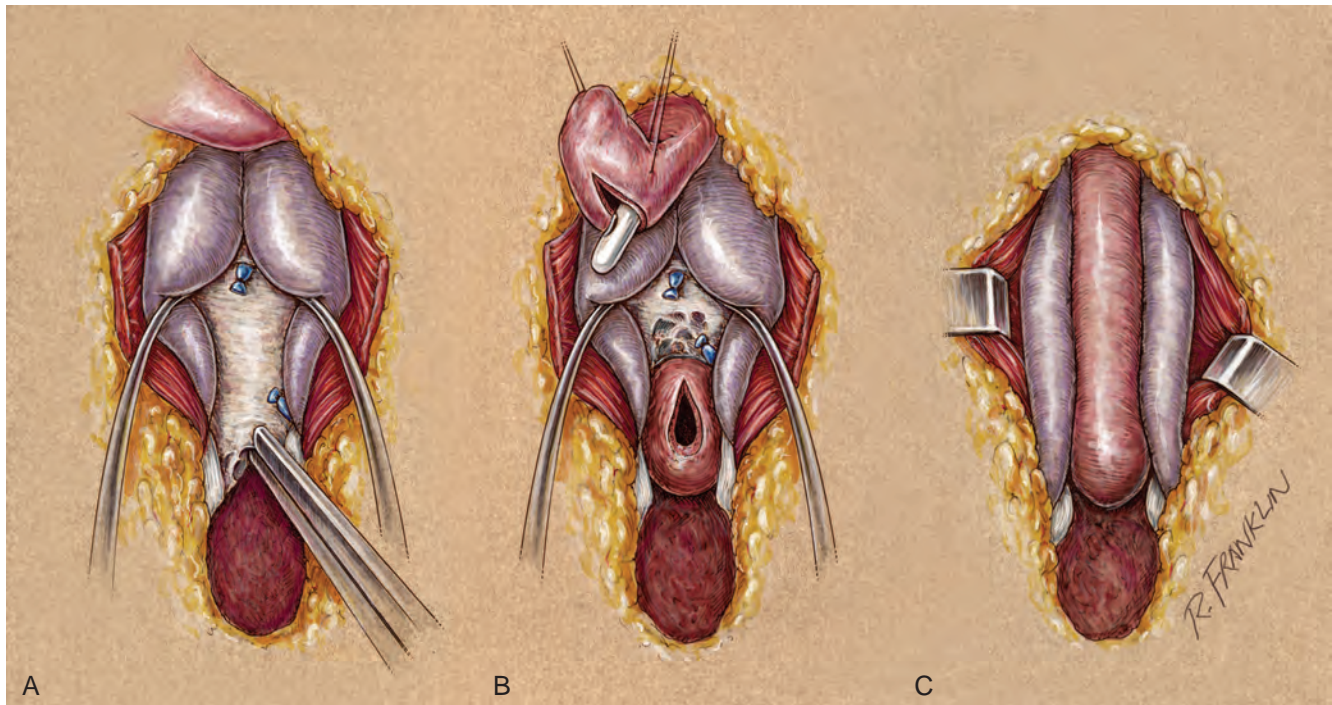

Figure 40-37. Infrapubectomy. If the prostate is elevated behind the symphysis pubis (A), the inferior aspect of the symphysis is resected with a Kerrison rongeur. As much of the bone can be removed as necessary (B) to afford a simple approximation of the ends of the urethra (C).

Figure 40-38. Resection of the pubis and rerouting of the urethra around the crus. When the prostate is markedly displaced, it may be necessary to expand the infrapubectomy. Sometimes, despite separation of the crura to the full extent possible, the two ends of the urethra do not meet when they are brought directly through the crus. It is necessary to bring the urethra lateral to one of the crura to make up this length.

to be valuable in observing these patients. In many cases (anterior urethral reconstruction), we have found that retrograde urethrography is more confusing than helpful.

With the use of the techniques discussed or similar techniques, curative rates for reconstruction of posterior PFUIs are in the high 90% range. In large centers, failures are not due to technical problems (i.e., anastomotic restenosis). In general, failures are indicative of ischemia of the proximal corpus spongiosum with ensuing stenosis of the mobilized corpus spongiosum. This occurs because, with mobilization, the corpus spongiosum, in essence, becomes a flap with the vascular pedicle being the retrograde vascularity from the arborization of the dorsal arteries through the glans (Fig. 40-39).

We have studied this phenomenon in trauma patients and have arrived at conclusions that we believe allow us to predict the patients at risk for this ischemic atrophy phenomenon. Initially, we used pudendal angiography to study all trauma patients who seemed to be at risk for bilateral deep internal pudendal artery injury at the time of trauma. These were patients who had evidence of injury to the dorsal penile nerves, patients in whom reconstruction had failed at other centers, patients with lateral impact pelvic fractures, and patients whose pelvic fractures were of the “wind-swept” variety (Brandes and Borrelli, 2001). We found that many patients had evidence of either unilateral or bilateral pudendal artery lesions, but that most had evidence of vascular reconstitution. Patients with an intact pudendal artery on one side often were potent and were reliably cured with reconstruction. Patients with only reconstituted vessels, either unilateral or bilateral, never were potent but were reliably reconstructed. We found that these patients were optimal candidates for penile arterial revascularization to improve potency. Because we noted this relationship to potency, we began evaluating patients with duplex ultrasonography. We found that patients with normal unilateral or bilateral pudendal arteries demonstrated normal arterial parameters on duplex evaluation. Patients with only reconstituted bilateral or unilateral arteries never had normal arterial parameters on duplex ultrasonography.

Figure 40-39. Diagrammatic representation of the deep vasculature of the penis. **A**, In the normal situation, through the common penile artery, flow is directed to the tip of the penis with arborization into the spongy erectile tissue of the glans penis. This provides retrograde flow into the corpus spongiosum. If the arteries of the bulb are intact, there is also antegrade arterial flow to the corpus spongiosum. **B**, With interruption of the arteries to the bulb and mobilization of the corpus spongiosum, all flow to the corpus spongiosum is retrograde through the common penile arterial system. **C**, In hypospadias, the distal corpus spongiosum may have been interrupted, with proximal mobilization of the corpus spongiosum and division of the arteries to the bulb. Even if the common penile circulation is intact to the tip of the penis, it may not adequately provide retrograde vascularity to the corpus spongiosum; ischemic stenosis can ensue. **D**, In the case of injury to the common penile artery, with elevation of the proximal corpus spongiosum and division of the arteries to the bulb, blood flow to the proximal corpus spongiosum may be inadequate, leading to ischemic necrosis or ischemic stenosis.

This information allows us to proceed to pudendal angiography only in patients with abnormal arterial parameters on duplex ultrasonography; patients with normal findings on ultrasonography predictably do well with reconstruction. Our data also show that patients do well with reconstruction if they have at least one side that is reconstituted, and the only patients at risk for ischemic stenosis are patients with bilateral complete obstruction of the internal pudendal vessels. In such patients, we perform penile arterial revascularization to augment the vascularity and, with that accomplished, proceed to urethral reconstruction (Jordan, 2005; Davies et al, 2009; Zuckerman et al, 2012). In many cases of pelvic fracture urethral distraction defects, erectile dysfunction is a consequence of the injury, although erectile dysfunction clearly results from the reconstructive surgery in some patients. We think that the incidence of injury to the pudendal arteries is drastically underreported and under-recognized. We and others believe that in many of these cases, the cause of erectile dysfunction is vascular (Brandes and Borrelli, 2001). However, there are at least a portion of patients

with neurogenic erectile dysfunction following PFUI, as some men experiencing ED following PFUI will have normal arterial inflow (Shenfeld et al, 2003; Metze et al, 2007).

Summary

Using the maneuvers outlined, we have found that virtually all distraction injuries can be reconstructed through a perineal approach with an anastomotic technique. Although the above-and-below approach is used when concomitant bladder neck surgery is performed, the inability to identify these patients accurately has led us to perform bladder neck surgery at a second setting. We have abandoned a transpubic approach as applied to posterior urethral distraction injuries.

Although we favor primary reconstruction of posterior urethral distraction injuries, other authors choose to manage these injuries endoscopically (Barry, 1989). We have found that the endoscopic management of PFUIs is not a simple procedure and must be undertaken only by a skilled and experienced surgeon. Many of these procedures can be categorized as a “cut-for-light” procedure. Although some surgeons report success, most cut-for-light procedures are not done with sufficient precision to allow adequate realignment of the urethra. We have seen many disasters that have resulted from these procedures and in most cases condemn the use of these modalities. In addition, no cut-for-light series compares favorably, with regard to long-term success rates, with series from large centers that use primary anastomotic techniques (Levine and Wessells, 2001).

In 1989, Marshall described his method of using stereotactic techniques for endoscopic alignment of the ends of the urethra. He emphasized the length of time it takes to obtain precise alignment before undertaking the endoscopic portion of the procedure. In his procedure, he passed a wire through the aligned ends of the urethra, minimally dilating the channel and widening it with transurethral resection. The scar is stabilized by a period of self-catheterization. While technically feasible, this approach has limited applicability for most patients. Patients whose medical condition, age, or concomitant orthopedic injury prevents them from being placed in the exaggerated lithotomy position or reconstructed using a transpubic approach may be managed with this technique.

In children, the goals of surgery are the same as in adults. In our experience, most children can undergo reconstruction by the same perineal exposure as used in adults. Exposure is more difficult, but nonetheless perineal anastomosis can be done (Hafez et al, 2005). However, the posterior, sagittal transsphincteric approach has been proposed as a better approach in children (Mathews et al, 1998; Peña and Hong, 2004). We agree that the posterior approach is an elegant method of exposure; however, with this approach, we have observed that surgeons tend to resort to techniques of substitution reconstruction where primary anastomosis could be done and, in our opinion, is superior. With our experience accumulating using the vessel-sparing approach to anterior urethral reconstruction—primary anastomosis and augmented anastomosis—we have extended the technique to select patients with pelvic fracture urethral reconstruction and have found the approach feasible with good results in a small number of patients. However, the advantage has not been proven.

VESICourethRAL DISTRACTION DEFECTS

Enthusiastic use of radical prostatectomy has led to increasing experience with patients who have had total obliteration of vesicourethral anastomosis. In some patients, there is distraction of the vesicourethral anastomosis with either a totally obliterating distraction defect or severe anastomotic stenosis. With increased use of robotic-assisted laparoscopic techniques we have seen a decrease in the number of significant anastomotic stenoses, and other authors have shown this as well (Breyer et al, 2010). This improvement may be secondary to reduction in anastomotic urine leaks, better mucosal

KEY POINTS: DISTRACTION INJURIES OF THE URETHRA

- Urethral distraction injuries are the result of blunt pelvic trauma and accompany about 10% of pelvic fracture injuries. In many injuries, there does not appear to be total distraction of the entire circumference of the urethra; instead, a strip of epithelium may be left behind.
- The use of aligning catheters acutely is controversial, but most clinicians would agree that the aligning catheter, at the very worst, facilitates subsequent reconstruction and, at best, often leaves the patient with an endoscopically manageable stenosis.
- As with any stricture, it is important to define the precise anatomy. The combination of contrast-enhanced studies with endoscopy and selective MRI is useful. The appearance of the bladder neck on contrast-enhanced studies or on antegrade endoscopy is not predictive of ultimate function of the bladder neck. Simultaneous reconstruction of the bladder neck and the posterior urethra is usually not undertaken at the present time.

apposition, and the running anastomosis allowed with the magnification and dexterity using the robotic approach.

As with other defects, it is important to determine the length of the defect accurately. This can be accomplished by simultaneous cystography with retrograde urethrography, simultaneous retrograde urethrography and antegrade endoscopy through the suprapubic tube, or both.

Numerous options are available for the management of these complex patients. Many of these patients have other medical problems, and it has been our observation that many have thick and small bladders, possibly contributing to the difficulty with the initial surgery. The ever-present issue of body habitus also must be considered and, in our opinion, contributes to problems with the initial anastomosis. An indwelling suprapubic tube must always be considered an option. In a patient who is significantly overweight, the results of aggressive reconstruction have not been good. The place for endoscopic techniques is covered later in this section; however, in the case of short-length distractions, we have had good success with aggressive incisions at the 3 o'clock and 9 o'clock positions followed in approximately 3 weeks with repeated incisions. Whether the holmium laser is better than the cold knife can be debated; the hot knife is unnecessary. If one must "core through" to establish continuity, endoscopic procedures have no place in our opinion except as discussed later. [Vanni and colleagues \(2011\)](#) published their experience with radial urethrotomy and intravesical injection of mitomycin C. They had an initial success rate of 72% in patients with recalcitrant strictures.

In some cases, a continent catheterizable bladder augmentation may be a better operation than aggressive functional reconstruction; in an obese patient, construction of a functional catheter channel can be difficult. Diversion must also be entertained, and in patients in whom functional reconstruction is not an obvious choice, it becomes a primary option.

If functional reconstruction is deemed possible, we think it is a reasonable choice, and our technique is as follows. We place the patient in a low-lithotomy position and use an abdominal-perineal combined approach. We make a lower midline incision, exposing the bladder and dissecting it from the lateral sidewall and further mobilizing the anterior bladder from beneath the pubis as aggressively as can be safely undertaken from above. We then open the peritoneum and develop the retrovesical space, again taking care to complete the dissection as safely as can be accomplished from above.

A second surgeon begins the perineal dissection by a curvilinear perineal incision similar to that used for a radical perineal prostatectomy. The dissection is posterior to the transverse perineal musculature (posterior anal triangle) and carried along the anterior rectal wall to the area where fibrosis is encountered from the prior

radical prostatectomy dissection. The impulse of the perineal surgeon's finger can usually be felt adjacent and lateral to the area of fibrosis and distraction at this point. In addition, the abdominal surgeon places a finger at the limits of the retrovesical dissection from above to provide another palpable landmark and to ensure a safe dissection anterior to the rectal wall and posterior to the bladder and trigone. The perineal dissection is joined to the abdominal dissection, and the rectal wall is completely peeled off the area of fibrosis associated with the distraction defect. We place drains between the rectum and the distraction defect, encircling the area of fibrosis.

The dissection beneath the pubis is made easier by the excision of an ellipse of the rim of the superior pubic ramus. Total pubectomy is not required. Partial pubectomy can be performed with the reciprocating attachment of the Aesculap surgical drilling device (Aesculap, Tuttlingen, Germany); this makes placement of the sutures technically straightforward and improves the exposure for the dissection and resection of the distraction fibrosis.

At this point, the bladder is opened, and the area of the bladder neck is determined. A sound is placed and advanced to the area of obliteration; this allows us to resect the well-defined area of fibrosis completely. The urethral stump is exposed and opened, and the site of the neobladder neck, having been identified, is opened. We marsupialize the bladder epithelium as described by [Eggleston and Walsh \(1985\)](#), place anastomotic sutures in the urethral stump, and pass a stenting catheter.

Before the vesicourethral anastomosis is seated, the omentum is mobilized and placed between the posterior wall of the anastomosis and the anterior rectal wall. We seat the anastomosis and wrap the omentum around the area of anastomosis, tagging it into place. The lateral vesical spaces are drained with closed suction drains, and a suprapubic tube is left in place when the vesicostomy is closed. We have been doing this procedure perineally with similar outcomes.

Postoperative care is the same as for a radical prostatectomy. Patients are discharged when their drainage and ambulation allow and their diet has been resumed. We evaluate patients 4 to 6 weeks postoperatively, with the stenting urethral catheter removed and the bladder filled by way of the suprapubic tube.

Because one attempt has failed in these patients, we generally are conservative with the timing of a voiding trial. In some cases, voiding trials are done at 2 to 3 weeks.

Our series continues to grow, and we continue to have excellent success in reconstruction. We have some patients who deem their continence adequate for their lifestyle; in the others, we have been successful with the placement of an artificial sphincter.

Other authors have proposed a different approach to these very difficult cases. In patients for whom multiple attempts at dilation or incision of these vesicourethral anastomotic stenoses have failed, [Elliott and Boone \(2001\)](#) proposed making an incision with placement of the UroLume endoprosthesis, followed at an interval by the placement of an artificial sphincter. They initially described nine men treated with this approach; seven of the men were satisfied with the results of their treatment at a mean follow-up of 17.5 months. Other authors ([Mark et al, 1993](#); [Kaplan, 2004](#); [Anger et al, 2005](#)) have proposed slight modifications of this approach and also report adequate patency and continence in these patients. With the removal of UroLume from the market, this approach is impossible.

COMPLEX FISTULAE OF THE POSTERIOR URETHRA

The increase in the performance of radical prostatectomy has also led to an increased incidence of vesicorectal or vesicourethrectal fistulae. In most cases, these are small and managed by a transperineal, transanal-transsphincteric, or posterior approach. However, some cases are complex, with the fistulae associated with large granulated cavities. The problem is magnified when radiation (brachytherapy, external beam therapy, or both) is part of the equation. With radiation fistulae, many centers

have gone to diversion with ileal conduit or bowel pouch as opposed to functional reconstruction. These cases have also been managed with the approach described earlier for vesicourethral distraction problems. However, the omentum serves an even more important purpose in these cases. In addition, with the increasing application of “minimally invasive” modalities for carcinoma of the prostate (i.e., brachytherapy, combined brachytherapy with external beam irradiation, higher dose external beam irradiation, and cryotherapy), the magnitude of complexity of these problems of prostatic urethral fistulae, granulated cavities, and severe rectal injury continues to increase. We have tried to approach these problems aggressively, with preservation of function where possible.

In many of these cases, salvage prostatectomy can be combined with rectosigmoid resection. In some cases, we have successfully reanastomosed the bladder to the membranous urethra. Preservation of continence has been mixed. In cases in which vesicourethral anastomosis is impossible, a urachal-peritoneal flap combined with a rectus abdominis muscle flap is used to bolster the closed bladder neck and to keep the closed bladder neck from sticking to the back of the pubis. The bladder is augmented, and a continent catheterizable channel is developed. In some cases, the continuity of the colon cannot be reestablished, and a colostomy is performed as distally on the descending portion of the colon as possible. Whenever continuity of the colon can be reestablished, a J-pouch coloanal anastomosis is done. Omentum is used to envelop the rectal closure or to separate the rectal closure from the vesicourethral anastomosis. The combined abdominal-perineal approach that was previously described provides excellent safe exposure for management of these complex situations. The morbidity of this approach has been acceptable.

One must be careful in addressing the irradiated bowel. We had a patient who did well with his surgery for continent catheterizable augmentation and bowel closure, but when his colostomy was reversed, he developed an overwhelming colitis and a re-fistula, with an eventual septic death. Another patient had a breakdown of his bladder neck closure and to date remains with a large vesicoabdominal fistula. These cases must be individualized. When they go well, they go wonderfully well; when they do not, they become a disaster for the patient, the patient's family, and the surgeons involved.

Zinman reported a 10-year experience with the management of rectourethral fistulae (Vanni et al, 2009). The series comprised 33 patients who had fistulae and who had not undergone irradiation and 33 patients who had undergone irradiation. Mean follow-up for the entire series was about 20 months. The review was a retrospective review taken from office records and hospital records. All fistulae were repaired by an anterior transperineal approach using gracilis muscle interposition flaps and in some cases with a buccal graft. In this series, 100% of the nonirradiated fistulae were successfully closed with a mean follow-up of 20 months, 85% of the irradiated fistulae were closed in a single stage, and 12% required an additional procedure, with an ultimate closure rate of about 97%. In the nonirradiated group, there were no urethral strictures noted with long-term follow-up; five recurrent strictures were noted in the irradiated group. In the nonirradiated group, 91% of the patients had their bowel undiverted. In the irradiated group, 39% had long-term bowel diversion. Zinman believes that the use of muscle interposition flaps are integral to achieving good results, and the use of buccal mucosal grafts, where needed to augment the closure of the urinary tract, was also believed to be invaluable (Vanni et al, 2009). An estimation of ultimate urinary and bowel function is integral to the determination of the plan for reconstruction or diversion, or both. Also, the surgical approach chosen facilitates and limits options (i.e., of the bowel, the urethra, or tissue interposition) (Lane et al, 2006).

CURVATURES OF THE PENIS

Normal elasticity and compliance of all tissue layers of the penis are critical for erectile function, tumescence, and rigidity. Tissues

KEY POINTS: VESICourethRAL DISTRACTION DEFECTS AND COMPLEX FISTULAE OF THE POSTERIOR URETHRA

- Vesicourethral distraction defects are a complication of radical prostatectomy.
- There are many options for management of these complex patients. An indwelling suprapubic tube must always be considered a long-term option. Likewise, in some cases, a continent catheterizable bladder augmentation may be a better operation than aggressive functional reconstruction. If functional reconstruction is deemed reasonable, we have employed an above-and-below technique, in which laparotomy is combined with a posterior perineal triangle dissection.
- The interposition of omentum has been used for distraction defects and for complex fistulae. This approach allows safe mobilization of the rectum from the area of the distraction scar or from the fistula site.
- When radiation is added, the complexity of reconstruction is magnified. The effects of radiation must be allowed to settle; tissue interposition is the rule, and functional reconstruction is impossible in many cases. Some think that diversion, in the case of patients who have received radiation, is the safest and best option.
- Careful consideration of ultimate urinary and bowel function is integral to proper planning of surgery.

must expand in all dimensions as the penis engorges with blood; eventually, the tissues of the tunica albuginea and the septal fibers of the corpora cavernosa are stretched to the limits of their compliance, and tumescence is converted to rigidity. In the normal penis, the tissues are symmetrically elastic, and the erection is straight. In curvature of the penis, there is relative asymmetry of one aspect of the erect penis. In some cases, this condition arises from diminished compliance of one aspect of the tunica albuginea or outright foreshortening of one aspect of the erectile bodies.

The term *chordee* means curvature, but it is commonly used as if it refers to the tissues causing the curvature. This misuse of the term is seen in the statement “the chordee was resected”; properly phrased, the statement should be “the chordee can be corrected by resecting the inelastic tissues that are causing the chordee.”

Curvatures of the penis can be congenital or acquired. Some confusion also exists in common usage of the term *congenital curvature of the penis*. The terms *congenital curvature of the penis* and *chordee without hypospadias* have often been used interchangeably. We prefer to reserve the term *chordee without hypospadias* for patients in whom the meatus is properly located on the tip of the glans penis; a ventral curvature is associated with abnormalities of the ventral fascial tissues or corpus spongiosum, or both. It has long been recognized that hypospadias is a condition that is associated in some patients with either a diminutive penis or a micropenis. Although a small penis is not diagnostic of hypospadias, it is highly unusual for a patient with hypospadias to have an exceptionally large erect penis. In contrast, other congenital curvatures of the penis (ventral, lateral, or dorsal) are inevitably associated with the finding of a large erect penis. Because the trauma that results in acquired curvature is virtually always associated with intercourse, the occurrence of acquired curvature is nil before the onset of puberty. We have seen some patients in whom there was a history of trauma during vigorous masturbation, but these patients are the exception. Similar to congenital curvatures of the penis, acquired curvatures may be dorsal, lateral, ventral, or complex.

Types of Congenital Curvature of the Penis

Please see the Expert Consult website for this section.

The urethra begins as an epithelial groove in the midline of the ventral surface of the developing penis. As the groove extends, it deepens, with the edges eventually meeting to fuse into a tube. Fusion begins proximally and progresses distally. During normal development, the fusion of the urethral tube eventually reaches the tip of the glans penis. Proliferating mesenchyma surrounds the tube, separating it from the skin, and differentiates to form the corpus spongiosum, Buck fascia, dartos fascia, and overlying ventral skin of the penis. Fetal development of the penis is regulated by testosterone, produced by the fetal testis, which is converted by 5 α -reductase to dihydrotestosterone. Dihydrotestosterone acts directly on cells with androgen receptors and on all layers of the male external genitalia. This embryologic process explains the development of the anterior urethra that is unique to males.

Maturation of these tissues into normal structures depends on the same growth factors that control the formation of the urethra. Although urethral development has progressed normally, mesenchymal tissue development in the penis may be deficient or abnormal and result in dysgenetic and inelastic fascial layers. In 1973, Devine and Horton proposed a typing classification for the various congenital curvatures. In type I congenital curvature, the urethral meatus is at the tip of the glans. However, none of the surrounding layers are normally formed, and the epithelial urethra is associated with maldevelopment of the corpus spongiosum and all the tissues superficial to the urethra. Skin coverage of the epithelial tube is present. In type II, a dysgenetic band of fibrous tissue thought to be derived from the mesenchyma, which would have produced the Buck fascia and the dartos fascia, lies beneath and lateral to the urethra. However, the urethra is contained within a normally developed and fused corpus spongiosum.

In type III, the urethra, corpus spongiosum, and Buck fascia all are normally developed and ventrally fused. However, there is a short area of inelastic tissue in the dartos layer of the penis that causes a relatively sharp bend. Abnormal development of the dartos fascia is frequently associated with complex curvatures. With extensive involvement, the inelastic dartos can be sufficient to restrain the penis and conceal the penile shaft. In many of these cases, there appears to be abnormal prominence of the mons fat pad. These stigmata are thought to be associated with an abnormality in the proper progression of virilization during fetal development.

In type IV, although the urethra, corpus spongiosum, and fascial layers are normally developed, there is relative shortness or inelasticity of one aspect of the tunica albuginea of the corpora cavernosa.

Experience has shown that most patients whose congenital curvature is type IV seem to demonstrate evidence of a hypercompliance of the tunica albuginea. In these patients, the flaccid penis is normal in size and not impressively large, whereas the erect penis is large. The tunica albuginea of the corpora cavernosa is required to expand through a wide range, and if there is asymmetry in the compliance of the tunica, curvature occurs. Patients with type IV curvature commonly notice curvature before puberty; as puberty progresses, an increase in the curvature is noted because of the penile hypertrophic growth spurt that occurs during this time.

Type V congenital curvature is also known as congenital short urethra. This term implies that there has been correct fusion of all elements of the penis (i.e., tunica albuginea, urethral epithelium, corpus spongiosum, Buck fascia, dartos fascia, and ventral skin). However, during erection, the correctly fused urethra and corpus spongiosum are not long or compliant enough to match the compliance of the other ventral tissue layers.

If type V congenital curvature exists at all, it occurs so rarely that when it is encountered, one should doubt the findings. Although discussion of the condition in the past has centered on the best location to "cut the urethra" during the repair, on the rare occasions when this condition is encountered, it is our belief that it should be diagnosed and treated only by the most experienced surgeons. In general, if the urethral meatus has developed to the tip of the glans, the urethra should not be divided to correct ventral curvature of the penis. Although there will be extremely rare exceptions to this bold statement, if those exceptions are encountered, their existence should still be questioned.

Congenital curvature types I, II, and III represent forms of the hypospadias anomaly, and we prefer to refer to them collectively under the term *chordee without hypospadias*. This term implies that although the meatus is not improperly placed, curvature is due to inappropriate fetal development of the ventral penile structures. We prefer to refer to the type IV anomaly as **congenital curvature of the penis**. If a patient has findings of hypercompliance of the corpora cavernosa and a ventral curvature, the diagnosis is congenital ventral curvature of the penis; if the hypercompliance causes a lateral curvature, it is referred to as congenital lateral curvature of the penis (left or right). Although, as mentioned, the type V anomaly is so rarely encountered that it deserves its own diagnosis, we believe its correction is best discussed with types I, II, and III, under the category of *chordee without hypospadias*.

Chordee without Hypospadias in Young Men

Please see the Expert Consult website for this section.

Congenital Curvatures of the Penis

Patients with congenital curvature of the penis can have ventral, lateral (which is most often to the left), or, unusually, dorsal curvature. Photographs of the erect penis demonstrate a smooth curvature that generally involves the entire pendulous portion of the penile shaft.

Patients are usually otherwise healthy young men between the ages of 18 and 30 years. Many of these patients have noticed curvature before passing through puberty but have presumed it to be normal. However, with puberty, they discover that the curvature is not normal; or they become sexually active and discover that the curvature impedes their efforts; or they notice increasing curvature as they pass through puberty, and this, in their minds, clearly would preclude sexual intercourse. Occasionally, a patient waits until he is older than 30 years to deal with the anomaly; even less often, a younger adolescent may discuss his genitalia with his parents.

In circumcised patients, we make an incision through the circumcision scar, which in many cases is displaced well down on the penile shaft. However, even with relatively significant displacement of the circumcision scar on the shaft of the penis, the reincision should be through the circumcision scar. The penis is degloved by dissection of the layer immediately superficial to the superficial lamina of Buck fascia.

An artificial erection is obtained with normal saline infusion or pharmacologic agents. We do not routinely recommend a tourniquet device because constricting devices can conceal the proximal limits of the curvature; this is of most significance in cases of ventral curvatures, which frequently extend proximally. Occasionally, some element of perineal pressure is initially required, but these are patients with normal erectile function, and venous occlusive function is normal. The artificial erection demonstrates the character of the curvature and the location of maximal curvature. In patients with ventral curvature, there may be some illusion of thickening of the dartos and Buck fascia, and in these patients, the fibrous tissue is mobilized and completely excised. The corpus spongiosum is detached from the corpora cavernosa and mobilized from the glans to the penoscrotal junction.

After these tissues are excised, the artificial erection is repeated, and an occasional patient is found to have complete straightening. However, most patients experience a differential elasticity between the dorsal and the ventral aspects of the corporeal bodies, and although the curvature may have been lessened, it persists unless further procedures are done to straighten the penis.

In an adult patient with persistent curvature, there are two options for surgical correction: (1) to lengthen the ventral aspect of the penis by making transverse incisions in the ventral tunica and placing an autologous tissue graft (we currently use the small intestinal submucosal graft at our institution), and (2) to shorten the dorsal aspect of the penis by elevating the neurovascular bundle, excising an ellipse or ellipses from the dorsum of the tunica albuginea, and closing the defects in watertight fashion ([Nesbit procedure \[Nesbit, 1965\]](#)). **Because the size of the erect penis is usually not a problem in these cases of congenital curvature, we have chosen the second option and strenuously discourage ventral grafting in these patients.** The recovery period after this procedure is much shorter, and the variabilities of graft take do not have to be considered. In addition, when a graft is used, there is always the possibility, although uncommon, of the development of graft-induced veno-occlusive dysfunction. **In a 2000 consensus conference sanctioned by the World Health Organization, the committee on Peyronie disease and congenital curvature of the penis agreed that most, if not all, cases in men with the classic finding of congenital curvature of the penis were best managed with plication or corporoplasty techniques but not grafting techniques ([Jardin et al, 2000; Lue, 2004](#)).** This consensus was reiterated at the next World Health Organization conference. It is preferable to

shorten the longer aspect of the penis in patients with congenital curvature. However, **if the patient falls into the category of chordee without hypospadias and shortness of the penis is an issue, we selectively use incisions with grafts to correct the curvature ([Devine and Horton, 1975](#)).**

After the decision has been made to proceed with excisions of ellipses of dorsal tunica, Buck fascia can be elevated, in concert with the dorsal neurovascular structures, by beginning just lateral to the corpus spongiosum and carrying the dissection dorsally across the midline. Alternatively, the tunica can be exposed by excising the deep dorsal vein of the penis and opening the inner lamina of Buck fascia. Elevation of the neurovascular structures is done by dissecting from the dorsal midline laterally around to the corpus spongiosum and from the coronal margin to the penopubic junction, limiting the effects of stretching the dorsal structures with exposure of the dorsum of the penis.

An artificial erection is obtained to plan the proposed ellipse excisions. We prefer to use several small ellipses rather than try to correct the curvature with one large ellipse. The first ellipse is usually positioned at the point of maximal concavity. The edges of the planned ellipse are apposed with a Prolene suture. The artificial erection is repeated to assess the effects of that excision. If there is good straightening in that area of the shaft, the incisions are again well marked, the plicating sutures are removed, and the ellipses of tunica are made with a sharp scalpel blade. By dissection in the space of Smith and removal of only an ellipse of tunica, the ellipses are carefully excised to avoid damage to the underlying erectile tissue or can be merely closed under the reapproximated edge of the defect in the tunica albuginea. The edge of the ellipse is reapproximated with a combination of interrupted 4-0 polydioxanone sutures and a watertight running 4-0 polydioxanone suture.

After closure, we repeat the artificial erection to assess the results of the first ellipse with the others. A final artificial erection should demonstrate the penis to be perfectly straight. In cases of ventral curvature or when complex curvatures are associated with an element of ventral curvature, a minimal degree of dorsal curvature after correction is acceptable. In most cases, as the sutures dissolve, the penis either remains minimally dorsiflexed or becomes perfectly straight.

The Buck fascia is closed. Two small suction drains are placed superficial to the Buck fascia but deep to the dartos fascia. We replace the skin sleeve, with its edges apposed with interrupted small Vicryl or Monocryl sutures. In all patients, we place a small Foley catheter and a small suction drain, and both are removed on the first postoperative day. Depending on the amount of edema and drainage, patients are discharged from the hospital on the evening of the first postoperative day or early the second postoperative day.

A congenital lateral curvature of the penis is often associated with some complexity of curvature; patients frequently notice lateral curvature in association with a ventral or, less commonly, a dorsal curvature. However, some patients present with only lateral curvature, with the right side larger than the left, and curvature to the left.

In some cases, a repair of the lateral curvature can be approached through a small incision at the point of maximal curvature. Laterally placed incisions on the penile shaft are not cosmetically optimal. We prefer a degloving incision after exposure of the deep penile structures; the point of maximal concavity is then marked. Prolene sutures are placed, and an artificial erection is performed again. The size of the ellipse is assessed, and the ellipse is excised and closed as discussed earlier.

As mentioned, most cases of lateral curvature are associated with complex curvatures. In these patients, the correction of the curvature is similar to that described for patients with ventral curvature, with incision through the circumcision scar with the skin reflected. In contrast to a ventral curvature, with a lateral curvature, the entire dorsal neurovascular bundle does not need to be reflected; it is seldom required and it is not considered beneficial to excise the deep dorsal vein in approaching the dorsum of the penis. The postoperative care is the same as described for a ventral curvature. For the uncommon patient with a congenital dorsal curvature of the

Patients with chordee without hypospadias usually present with either ventral curvature or ventral curvature associated with torsion (complex curvature). These young men do not typically have a greater than average stretched penile length (13.1 cm) (Schonfeld and Beebe, 1942) and will have noted curvature throughout life. If prepubescent, they have obvious curvature with erection; if postpubescent, they may offer a history of increasing curvature as they pass through puberty.

In many cases, there are abnormalities of the ventral penile skin. These abnormalities might consist of either an element of hooded preputial skin or a high insertion of the penoscrotal junction. Although patients have fusion of the preputial skin, there is also often a wrinkled appearance dorsally that we now recognize to be a form of the classic hooded preputial skin. In addition, in many cases, the tissues on the ventrum of the penis seem inelastic as the patient's penis is examined on stretch. This palpable inelasticity on the ventral penis consists of dysgenetic tissue, which can replace the Buck and dartos fascia layers; in some cases, there is an element of inelasticity of the tunica itself.

During surgical exploration, Devine and Pepe (unpublished data) obtained tissue from patients for evaluation of 5 α -reductase levels. Their data suggested a deficiency of the enzyme in the ventral dysgenetic tissue. Similarly, Silva and coworkers (2013) found reduced levels of androgen receptors in the urethral mucosa in patients with hypospadias compared with control subjects. El-Galley and colleagues (1997) also looked for growth factor deficiency in tissues of male patients with hypospadias and found a correlation. However, to our knowledge, a growth factor analysis has not been undertaken in patients with chordee without hypospadias.

An important part of the preoperative evaluation is the submission of instant or digital photographs of the erect penis, taken by the patient, documenting the curvature. The photographs are especially helpful in differentiating between the patients we refer to as having chordee without hypospadias and patients with congenital curvatures of the penis. In a patient who has chordee without hypospadias, the photograph reveals an erect penis commensurate with the size of the detumesced penis, whereas in a patient with congenital curvature, the erect penis is noticeably large. It is important to address the psychologic aspects of the condition as an integral part of the treatment; many of our patients see a psychologist preoperatively. Corrective surgery for chordee without hypospadias is highly successful, and an effective correction can be accomplished

in almost all cases with a single operation (Devine et al, 1991). In some cases, the penis has been straightened by excision of all the dysgenetic tissues from the ventral side of the penis and wide mobilization of the corpus spongiosum from the glans penis into the perineum.

Even in patients with obvious abnormalities of the corpus spongiosum (i.e., poor ventral fusion or frank bifid corpus spongiosum), wide mobilization usually reveals that it is not the corpus spongiosum that remains as the ventral limiting factor. In most patients, the penis remains curved because of the inelasticity of the ventral aspect of the corpora cavernosa themselves. In an occasional patient, the corpus spongiosum becomes atretic distal on the shaft, and the urethra itself is only an epithelium-lined tube. Even in these patients, with wide mobilization of the epithelial distal portion and elevation of the proximal corpus spongiosum, it is unusual to find the corpus spongiosum or the epithelial tube limiting the ventral erection. If the epithelial tube has served as an adequate urethra (i.e., it is not stenotic), the morbidity of urethral division and subsequent need for urethral reconstruction must be considered before such a procedure is undertaken. Because the evolution of hypospadias repairs accomplished by wide mobilization of the corpus spongiosum and epithelial and corpus spongiosal elements distal to the meatus has allowed onlay procedures, the morbidities of urethral division must be strongly considered and, we believe, usually avoided.

In children, after mobilization and excision of the dysgenetic tissues, the residual chordee can usually be corrected by making a longitudinal incision, with a sharp blade, in the ventral midline of the corpora cavernosa while an artificial erection is maintained. The incision (midline ventral septotomy) often can be extended between the corporeal bodies for a significant distance, allowing the edges of the ventral tunica to move laterally. The penis noticeably straightens with erection.

If this maneuver is insufficient, the dorsal neurovascular structures can be mobilized in concert with Buck fascia, and a small ellipse or ellipses of dorsal tunica albuginea can be excised and closed with watertight plicating sutures. Caution is important when the dorsal neurovascular structures are mobilized; with poor development of the ventral structures, which occurs in some patients, the arborization of the dorsal arteries provides the dominant vascularity to the glans.

penis, the repair is best accomplished by mobilizing the lateral aspect of the corpus spongiosum to allow small ellipses lateral to the midline to be positioned on the ventrum of the penis, by the technique described before.

Although described as a method for plication for curvature associated with Peyronie disease, corporoplasty, a procedure described by Yachia (1993), is also useful for the correction of congenital curvatures. The procedure consists of longitudinal incisions in the tunica albuginea with transverse closure. The “long side” is pliated without the need for excision; however, the plication is durable in that the tunica is opened and closed with a resulting scar, rather than reliance only on the strength of sutures as originally described by Nesbit (1965). With this technique, closure is done with absorbable monofilament suture.

Acquired Curvatures of the Penis

Acquired curvatures of the penis inevitably follow trauma to the penis. Many of these cases are associated with Peyronie disease, also believed to be associated with trauma to the penis during intercourse (Bella et al, 2007). Patients occasionally present who have had vigorous internal urethrotomy, with the incision extended outside the urethra and corpus spongiosum and involving the tunica of the corporeal bodies, causing scarring that is significant enough to be associated with curvature.

Acquired Curvatures of the Penis That Are Not Peyronie Disease

When a young man presents with an acquired curvature of the penis, one must always consider Peyronie disease. However, many men do not have true Peyronie disease. These patients, on close questioning, reveal a history of minimal lateral curvature of the penis and a clear memory of a lateral buckling injury that occurred during intercourse. In some cases, the patient remembers hearing a “snap” and notices immediate detumescence and significant ecchymosis of the penis. These patients are often referred with a diagnosis of Peyronie disease, but a diagnosis of curvature secondary to penile fracture is more accurate. Because of the noticeable events associated with fracture of the penis, many patients present acutely, and reconstruction can be accomplished at that time.

Occasionally, a patient or his primary care physician ignores the stigmata of the trauma (often described as “minimal” by patients), and the patient presents with a noticeable lateral scar that causes indentation of the lateral aspect of the penis and, in some cases, curvature. Patients who had preexisting lateral curvature may notice that their penis has been straightened by the trauma, but they are disturbed by the concavity caused by the scar. In others, the small linear scar causes a significant lateral curvature.

Another group of patients presents after a similar buckling trauma to the penis but without associated detumescence or ecchymosis. These patients report noticing that their erections were painful for a period after the trauma, and then a nodule developed in the lateral aspect of the penis. Eventually, they present with a lateral linear scar that has led to curvature and indentation at the site. We refer to this injury as a subclinical fracture of the penis.

The lesion of a subclinical fracture of the penis is believed to be due to the disruption of the outer longitudinal layer of the tunica albuginea during the buckling trauma. The inner, circular layer is not disrupted and maintains the blood-tight continuity of the corpus spongiosum. Another possible scenario is that both layers of the tunica albuginea are disrupted, but the overlying Buck fascia maintains its integrity. Some patients notice a pop with intercourse and a period of pain with erections, followed by curvature of the penis—usually dorsal. These patients probably tear the septal insertion completely. These patients have a similar presentation to patients with Peyronie disease.

Patients usually have normal erectile function after subclinical or clinical fracture of the penis; there does not appear to be an association with concomitant global cavernosal veno-occlusive

dysfunction. However, the association of cavernosal veno-occlusive dysfunction and trauma of the penis continues to be seen, and some patients have significant problems with erectile dysfunction after fracture-type injuries of the penis. These injuries are not associated with shortening of the penis. In most cases, the lack of erectile dysfunction and penile shortening help distinguish these patients from patients with Peyronie disease. If a detailed history leads one to suspect blighted erectile function, erectile function should be evaluated before proceeding with surgery. At our institution, we evaluate these patients with duplex ultrasonography and selectively with dynamic infusion cavernosometry and cavernosography.

Although foreshortening of the penis is not a characteristic of either the injury itself or the resulting scar in either of these injuries, these patients are not ideal candidates for contralateral plication procedures. This treatment would result in bilateral scars, which would cause bilateral indentations of the penis, and although the penis would have been straightened by the correction, most patients are upset by the cosmetic and functional result of a near-circumferential indentation of the penis. Instead, we excise the scar and place a graft to replace the corporotomy defect caused by the scar excision. Because these scars are on the lateral aspect of the penis, minimal mobilization of Buck fascia, associated dorsal neurovascular structures, and corpus spongiosum is required at the site.

The results of the surgical correction described have been extremely effective. Successful correction with a single operation has been achieved in all patients treated at our institution.

KEY POINTS: CURVATURES OF THE PENIS

- Curvatures of the penis can be acquired or congenital. Congenital curvatures of the penis can be categorized as chordee without hypospadias or congenital curvature of the penis.
- In general, chordee without hypospadias is a forme fruste of hypospadias. Although the meatus may not be abnormally placed, these patients usually have findings suggestive of hypospadias (i.e., malformation of the ventral structures of the penis). These patients are not characterized by large erect penises. In contrast, patients with congenital curvature of the penis seem to have exceptionally large erect penises.
- The entity of congenital curvature of the penis seems to be related to nonsymmetrical expansion of the erectile bodies, which must expand significantly during tumescence. Reconstruction in these patients generally is best accomplished by excision with plicating closure or pure plication techniques. The use of grafts is not recommended because of the unusual but real occurrence of graft-induced veno-occlusive dysfunction in certain patients.

TOTAL PENILE RECONSTRUCTION

General

The principal techniques of penile reconstruction were originally developed for treatment of trauma patients, and these patients were victims of war injuries in many injuries. In 1936, Bogaraz described a technique for phallic construction in a series of war-injured patients, and in 1944, Frumkin followed with a series from the Soviet Union. Aware of the work in the Soviet Union, Gillies and Harrison (1948) reported on a series of patients in whom they had accomplished penile reconstruction while stationed at a major hospital in the outskirts of London during World War II. In this series, numerous patients had a complete absence of the penis.

Initially, all procedures for phallic construction involved delayed formation and transfer of tubed abdominal flaps. These tubes were produced from random flaps of skin and because of their size were based on a tenuous blood supply. To allow new vascular patterns to become established in the transferred tissue, they were

formed in stages, with a “delay” between the stages. In the “tube-within-a-tube” design, the inner tube allowed the placement of a baculum during intercourse, and the outer tube provided skin coverage. Patients voided through a proximal urethrostomy. This approach continued to be the “state-of-the-art” phallic construction and penile reconstruction until 1972, when [Orticochea](#) described total reconstruction of the penis using the gracilis musculocutaneous flap. In 1978, Puckett and Montie reported a series in which they constructed the penis with a tubed groin flap. In the early cases in this series, the flap was transferred in delayed fashion to the area of the penile stump. Later in the series, a microvascular free-transfer technique was employed.

In 1984, Chang and Hwang popularized the forearm flap, based on the radial artery, for phallic construction. [Biemer \(1988\)](#) reported a modification of the forearm flap, which was also based on the radial artery; in 1990, [Farrow and colleagues](#) reported their “cricket bat” modification of the radial forearm flap. **At the present time, forearm flaps are the most commonly employed method for total phallic construction and penile reconstruction.**

The forearm flap is usually harvested from the nondominant forearm. Preoperatively, the Allen test is used to screen patients carefully for arterial insufficiency. This test involves palpation of the radial and ulnar arteries in the wrist, with the patient making a tight fist to express blood from his hand. As he opens his hand, the fingers are pale, but if palmar circulation is normal and both arteries are patent, the fingers turn pink when one of the arteries is released. On the basis of either the Allen test or the patient’s history, if there is any doubt about the integrity of the radial and ulnar arteries or the palmar arch, upper extremity angiography is performed.

As described, the forearm flap is a fasciocutaneous flap vascularized by the radial artery; however, the ulnar artery also vascularizes the forearm fascia and most of the forearm skin. The radial artery arises as a continuation of the brachial artery and proximally lies beneath the belly of the brachioradialis muscle, becoming more superficial at the wrist. The ulnar artery is also a continuation of the brachial artery and vascularizes a similar area of skin and underlying adipose tissue. The vascularity of the overlying skin is achieved by way of the underlying (antebrachial) fascia, which is the superficial fascia investing the musculature of the forearm.

The forearm flap can be elevated and transferred on the superficial fascia. The lateral and medial antebrachial cutaneous nerves appear proximally beneath the fascia. The cephalic, basilic, and medial antebrachial veins are also included in the flap and constitute a portion of the venous drainage. In some patients, the vena comitans is the dominant venous drainage system. At the time of flap transfer, it is imperative to assess the vena comitans and the superficial veins to determine which is the dominant system in the individual patient.

The various modifications of the forearm flap do not represent changes in the technique of flap elevation; rather, they are modifications in the design of the skin island and the relative position of the urethral paddle in relation to the skin that eventually becomes shaft coverage. Each of these modifications has advantages in different situations.

In the forearm flap as described by [Chang and Hwang \(1984\)](#), the shaft is covered with the radial aspect of the skin paddle. A de-epithelialized strip is made, and a second skin island, on the ulnar aspect of the skin paddle, is tubed to form the urethra. The urethral tube is rolled within the tube of skin to form a tube-within-a-tube design. In the white population, this flap has demonstrated a tendency to lead to ischemic stenosis of the lateral paddle, where the urethra is constructed.

In the cricket bat modification, the urethral tube extends distally, closely overlying either the radial or the ulnar artery. We have experience with elevation of the cricket bat modification on both arteries. Proximal to the urethral strip, a broader portion of the skin paddle provides coverage of the shaft. The urethral portion is tubed and transposed by inverting it into the center of the shaft portion of the skin paddle. The advantage of this modification lies in centering the urethral portion over the respective artery, in contrast to the Chinese design, in which the ulnar aspect is far distal from the radial artery,

with the potential for ischemic stenosis or loss of that portion. The cricket bat modification has been useful in trauma patients, particularly in patients who have a significant stump of erectile bodies and urethra left after the injury.

The modification by [Biemer \(1988\)](#) also centers the urethral portion of the flap over the artery. As described by Biemer, the flap is elevated on the radial artery and includes a vascularized piece of the radial bone intended to provide rigidity to the new penis. However, the inclusion of cartilage and bone has not been universally successful, and rigidity in these flaps is obtainable by the use of either an externally applied or an internally implanted prosthesis. If the bone is not elevated, the Biemer flap design can be elevated on either the radial or the ulnar artery. At our center, we most often elevate the flap on the ulnar artery, in a modification of the Biemer design.

Modifications of the Biemer design also include the glans construction technique that was originally described by [Puckett and Montie \(1978\)](#). In the original Biemer design, a central strip becomes the urethra, and lateral to that strip, two de-epithelialized portions and two lateral islands (lateral aspects of that skin paddle) are fused dorsally and ventrally to cover the shaft. With the modification of [Puckett and colleagues \(1982\)](#), a large island is left distally and flared back over the tip of the tubed flaps, creating the illusion of a glans penis. The Biemer design, especially when it is combined with Puckett’s design for glanular construction, offers the best cosmetic results ([Fig. 40-40](#)).

There are several disadvantages to the use of a forearm flap for phallic construction. The major disadvantage of forearm flaps is the obvious donor site deformity. We have reconstructed the donor site with full-thickness skin grafts taken from the area of the inguinal crease or buttock, and the cosmetic result is far superior to that obtained when the donor site is reconstructed with split-thickness skin graft (even thick split-thickness skin). Additionally, morbidity can be reduced with mobilization of the intact forearm skin to reduce the grafting requirement and attempts to minimize the step between the skin and muscle bed. A second disadvantage lies in the **possibility of the development of cold intolerance in the hand of the donor side.** Early in our experience with the forearm flap, we reconstructed the radial artery with an interposition vein graft. We have since abandoned this procedure in most of our series and have not seen cold intolerance in our patients. Another disadvantage occurs in male and virilized transgender patients **when the forearm skin is hirsute because the hair can be problematic** if it is included in the portion of the flap used for urethral construction. In such patients, we try to identify the potential for the problem and refer them for epilation before surgery.

[McRoberts and Sadove \(2002\)](#) proposed the use of the fibular osteocutaneous flap for phallic construction. The fibula is elevated on the periosteal vessel along with the overlying skin paddle. As they described, urethral reconstruction is by tubed graft techniques, and their procedure had a 100% urethral complication rate. [Kim and colleagues \(2009\)](#) used a radial forearm osteocutaneous flap in 40 patients with reasonable results, although for many patients the incorporation of bone did not provide sufficient rigidity for sexual function over time. For patients who need vascularized tissue only to cover the shaft of the penis, we have used the upper lateral arm flap. This is a fasciocutaneous flap, and its cutaneous vascular territory is centered on the radial collateral artery. The skin of the lateral upper arm is thin, with little subcutaneous adiposity. To mark the location of the lateral intramuscular septum and the course of the superior radial collateral artery, we draw a line joining the insertion of the deltoid with the lateral epicondyle. We begin the dissection posteriorly, elevating the superficial fascia until the posterior lateral portion of the intramuscular septum has been identified. A potential disadvantage of this flap lies in the fact that the entire venous drainage depends on the vena comitans, and although superficial veins do traverse the flap, none of them seems to provide significant venous drainage. We have found the flap to be completely reliable so far, with no losses secondary to venous insufficiency.

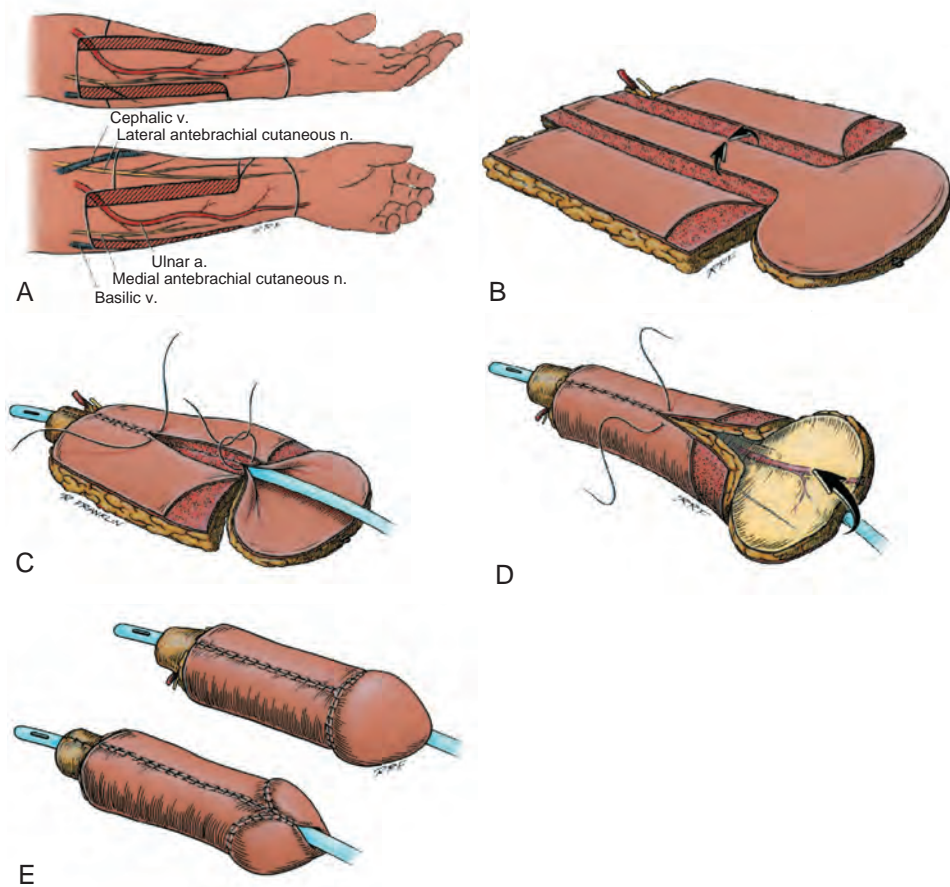

Figure 40-40. A, Schematic diagram of an ulnar forearm flap, modified Biemer design, on the patient's left (usually nondominant) forearm. B, Schematic of the elevated flap. The flap has been divided into skin islands by de-epithelializing the strips. Laterally are the shaft skin islands, medially is the urethral skin island, and distally is the integral glans, after the design of Puckett. C, Schematic of the configuration of the flap. Notice the urethral skin island has been tubularized to the level of the neomeatus. The lateral shaft skin islands are now in the process of being tubularized over the tubularized urethra. D, Schematic of the phallic flap as it is further configured. This view is of the dorsum. The ventral skin island has been closed over the urethra, and the dorsal skin islands are being collected. The integral glans will then be reflected over the dorsum of the flap. E, The appearance of the phallus after it is totally configured and transposed to the area of the "penis."

This flap has also been used for total phallic construction. For this purpose, the flap is expanded by tissue expander and elevated across the elbow, and the distal flap is elevated on the recurrent radial artery. As with the forearm flap, the donor site of an upper lateral arm flap can be disfiguring. However, because the scar is on the upper arm, it is more easily concealed beneath a shirtsleeve than a scar in the forearm. All the flaps described allow microneurosurgical coaptation of the flap cutaneous nerves with recipient nerves. With total phallic construction, the cutaneous nerves can be attached either to the dorsal nerves of the penis or to the dorsal nerves of the clitoris in a transsexual patient. When these nerves are unavailable, the nerves can be coapted to the pudendal nerve, which in most patients requires an interposition graft. These nerves are thought to provide the best restoration of erogenous cutaneous sensibility. We have also coapted the flap's cutaneous nerves to the ilioinguinal nerves, which provides sensation to the inner aspect of the thigh and the lateral aspect of the scrotum, and have achieved a reasonable degree of erogenous sensibility. The ilioinguinal nerve is also thought to provide a better degree of protective sensation (albeit less erogenous sensation) compared with the dorsal nerves (Monstrey et al, 2009).

In most patients, the deep inferior epigastric vessels are the recipient vasculature for flap transfer. These vessels are medial branches of the iliac system and lie on the dorsal (deep) aspect of the rectus abdominis muscle. The artery usually remains deep to the muscle, although an early penetration of the artery into the muscle can be observed in some patients. The artery classically bifurcates at the level of the umbilicus and is generally accompanied by two or more venae comitantes. These vessels have been elevated by several methods, and Lund and colleagues (1995) described their elevation for penile revascularization with laparoscopic techniques. When the deep inferior epigastric vessels are used, it is often necessary to include a saphenous vein for further venous runoff.

In some patients, these vessels are unavailable, and we have used a saphenous interposition graft to the superficial femoral artery. With use of this technique, we mobilize the saphenous vein well down the upper aspect of the thigh and then attach the vein to the femoral artery, making a temporary arteriovenous fistula. The fistula is divided, with the saphenous vein becoming the venous runoff and the interposition graft providing the arterial inflow. This system of recipient vessels is greatly inferior to a direct arterial anastomosis; because of this, in a few patients we have divided the profunda

femoris vessel and vigorously dissected it from its other branches. We have then performed an end-to-end (artery-to-artery) anastomosis of the ulnar artery to the profunda femoris. However, the long-term consequences to the patient of dividing the profunda femoris are unclear. Immediate reconstruction of the profunda does not appear to be advantageous because the dissection required to mobilize the profunda femoris to become a recipient vessel requires the division of numerous proximal branches, and these would not be reconstructed with an immediate reconstruction of the profunda femoris. Mention of this as a potential means of “creating” recipient vessels is not to recommend the procedure because the procedure may yet have unacceptable long-term consequences. Another option in extreme cases is to use the superficial femoral vein, which could be reconstructed with a vein interposition. When the “classic” recipient vessels are unavailable, these other methods may be acceptable. However, we strenuously caution concerning their use because the long-term consequences are unknown. We believe that division of the superficial femoral artery with immediate reconstruction is the preferable choice.

In the latter part of our series, we included the routine transfer of gracilis muscle to cover the area of the urethral anastomosis, increasing the vascularity to that area and significantly altering the incidence of anastomotic fistula and stricture formation. We also elevated a bipedicle flap from the area of the penile shaft base, which is transposed beneath the phallic flap. This flap provides increased bulk and some modicum of scrotal construction, and when it is combined with the gracilis muscle, its thickness provides excellent coverage for the juncture of the flap with the base of the neoscrotum. Mobilization of a tunica dartos flap with tunica vaginalis pedicle, or a Martius flap in a transgender patient, may obviate the necessity to elevate and transpose a gracilis muscle flap.

During the phallic construction procedure, urine is diverted by means of a suprapubic cystostomy tube, and the urethra is stented with a No. 14 soft silicone (Silastic) catheter. A voiding study is usually performed between the third and fourth postoperative week.

Outcomes after forearm free-flap phalloplasty have now been reported from several centers. Even in centers of excellence for phallic construction, complications and reoperations seem to be the rule rather than the exception. [Monstrey and colleagues \(2009\)](#) reported the largest single-stage radial forearm phalloplasty series with 289 patients over 15 years. Urologic complications were seen in 41% of patients, the most common being fistula in 25%, stricture in 8.7%, and both in 9% of patients. Stricture treatment in this series required a multitude of procedures to achieve a patent urethra; however, fistulae healed spontaneously in most cases. Tactile sensation was achieved in all patients, and many were sexually active.

Similarly, [Garaffa and coworkers \(2010\)](#) published a series from the United Kingdom on 112 patients undergoing total phallic construction with a radial forearm free flap. Reconstructions at this center are performed in stages rather than a single stage. The urethral anastomosis is deferred until several months after the flap has demonstrated stability. At a median 26 months of follow-up, 99% of patients who had achieved urethral continuity were voiding anatomically through the phallus. Despite staging the procedure, strictures still developed in 10% and fistulae in 24% of patients. Most patients (71.5%) developed phallus sensation.

Vascular complications and graft loss are the most feared morbidities associated with free-flap phalloplasty. These are rare events with rates of total flap loss ranging from 0.6% to 5% and higher rate of partial loss or limited skin necrosis ([Leriche et al, 2008](#); [Monstrey et al, 2009](#); [Garaffa et al, 2010](#)). Occasionally, minimal loss of the phallus is amenable to local wound care, but more often these cases require debridement and split-thickness skin grafting for coverage.

Rigidity for intercourse in a patient with phallic construction is usually achieved by either an externally applied or a permanently implanted prosthesis. Prosthetic implantation is never undertaken until 1 year after phallic construction because

protective sensibility must be demonstrated in the flap. When the flap is transferred, it is, by definition, rendered insensate. At about 3 to 4 months after reconstruction, as nerve regeneration occurs, sensation becomes noticeable. In addition, the urethra must be patent and proved to be durable before prosthetic implantation is undertaken.

At our center, we have a large series of patients with internally implanted devices. We have implanted hydraulic and articulated prostheses encased in Gore-Tex neocorpora. These devices are anchored to the ischial tuberosity and the pubis by anchoring the neocorpora to these bone structures. In most patients, we implant two cylinders or rods. Early in our series, we had problems with hematoma and seroma formation and subsequent infection. However, since modifying our antibiotic regimen and including the routine use of suction drains with the implant procedure, we have had excellent success with implantation. At the present time, we place the antibiotic-coated (Inhibizone) AMS 700CXR (American Medical Systems, Minnetonka, MN). The Titan prosthesis with hydrophilic coating and narrow base has also been used.

The largest published series describing the use of a mechanical prosthesis in a neophallus is from Belgium where a variety of prostheses have been put in 129 patients from 1996 through 2007 ([Hoebeker et al, 2010](#)). The proximal prosthesis was fixed to the pubic rami using either a Dacron sheath or permanent stitches through a rear tip extender. At a mean 30 months of follow-up, 41.1% of patients needed revision or explant for infection (11.9%), malfunction (13%), erosion/malposition (22.7%), or leak (9.2%). Complications are higher than seen for implants into normal corpora, which would be expected given that the neophallus has had extensive prior surgery, is not as well vascularized, and the device may be used more frequently in this traditionally young patient population.

We also have implanted testicular prostheses in many patients. In patients in whom we have used a hydraulic device, we have implanted the pump in one neohemiscrotum and a testicular prosthesis in the opposite one.

Reconstruction after Trauma

In many ways, the problems of trauma patients are more challenging to solve than the problems of patients who require total phallic construction. We have treated a large number of patients who have had devastating injuries to the penis after complicated prosthetic surgery or surgery to correct penile curvatures of Peyronie disease. The goal in these patients is to preserve the penile structures and function as much as possible and correct the deficiencies that are imposed on the patient by the trauma.

Acutely, urine must be diverted, necrotic tissue must be carefully debrided, and any foreign bodies that may have been implanted must be removed. Vigorous acute wound management stabilizes the wounds and allows active granulation to progress. In all trauma patients, an attempt should be made to save as many of the penile structures as possible.

Approximately 3 to 6 weeks after trauma, primary reconstruction can be undertaken, although we have elected to wait 4 to 6 months in some patients, depending on the situation. When significant adjacent tissue loss has occurred, the adjacent areas must be well reconstructed before proceeding with either phallic construction or penile reconstruction.

In a trauma patient, it is imperative that well-vascularized tissues be eventually transposed to the adjacent area, and reconstruction of these areas can be accomplished with numerous flaps. For groin reconstruction, the tensor fascia lata flap has been useful. The rectus femoris flap, characteristically long and large, can be transposed to the area of the lower abdomen and has been an extremely useful flap for inguinal and lower abdominal reconstruction. The gracilis muscle is an excellent flap for reconstruction of the perineum and the groin. Alternatively, the posterior thigh flap can be used for reconstruction of the groin and perineum and, in some cases, transposed to the lowermost portion of the lower

abdomen. The rectus abdominis flap is a useful flap and can be elevated with a vertical or transverse skin paddle. In addition, the flap can be transposed to either the ipsilateral or the contralateral side. Care must be taken in a patient who has had lower abdominal external beam irradiation.

Variations of the flap designs described for complete phallic construction have been successfully applied in select patients for penile reconstruction. An example is one patient who sustained an injury to his penis from a shotgun blast. The blast injured a large portion of the patient's right corpus cavernosum, and most of the penile skin was either destroyed or used for urethral reconstruction. In this patient, a flap based on the Chinese design was elevated. However, because the urethral reconstruction was accomplished with a penile skin island, the ulnar portion of the flap was not needed for that purpose. The ulnar portion was de-epithelialized and tubularized to form bulk and a new right corporeal body. This patient is now sexually active, and the bulk of the tube's dermal section gives adequate support to his penis for intercourse.

Another patient required only distal urethral construction and glans reconstruction. For this patient, we based a flap on the Biemer design to construct a glans. The proximal portions of the flap were de-epithelialized, allowing fixation of the neoglans on the tips of the corporeal bodies, and an excellent functional and cosmetic result was achieved for this patient. The versatility of free-flap technology allows the solution of complex issues with reasonably acceptable functional and cosmetic results.

FEMALE-TO-MALE TRANSSEXUALISM

Female-to-male transsexual patients present a unique challenge, and no patient should be considered for definitive reassignment surgery without having undergone complex screening and evaluation by a team consisting of mental health professionals as well as surgeons who are skilled in undertaking transgender surgery. It is imperative that an ongoing, stable, therapeutic relationship be established between the patient and a mental health professional at the time of definitive gender reassignment surgery. At our institution, the Harry Benjamin criteria (Ramsey, 1996) are strictly adhered to, and surgery is accomplished by a team of urologists, plastic surgeons, and gynecologists.

In most patients, the first stage of female-to-male transsexual surgery consists of bilateral salpingo-oophorectomy, hysterectomy, vaginectomy, and urethral lengthening with colpocleisis. Even in virginal patients, our surgeons have become skilled at accomplishing a hysterectomy and bilateral salpingo-oophorectomy by way of transvaginal surgery. We perform a vaginectomy at the same operation, leaving the anterior vaginal wall to be transposed as a random flap to lengthen the female urethra and allow colpocleisis. Lengthening of the female urethra brings the base of the native urethra up to what will be the base of the phallic flap; along with the transfer of gracilis muscle, it has significantly altered our surgical results with regard to urethral anastomotic fistula and stricture. Urine is diverted with a suprapubic tube, and a voiding trial is performed in approximately 21 days. Patients are generally in the hospital for 2 to 3 days and return 3 to 4 months later for phallic construction.

For phallic construction in a transsexual patient, we elevate a bipedicle flap of skin, as already described, from the area where the phallic structure will be implanted and transpose it to the undersurface of the neopenis. The patient is generally in the hospital for 10 to 14 days after total phallic construction, and a voiding trial with contrast material is done at about 28 days postoperatively. After 1 year, when erogenous sensibility is demonstrated and the urethra is proved to be durable, prosthetic implantation is considered.

KEY POINTS: TOTAL PENILE RECONSTRUCTION AND FEMALE-TO-MALE TRANSSEXUALISM

- The principal techniques of penile reconstruction originally were developed for treatment of victims of war injuries. Initially, all of the procedures involved delayed tissue transfer. In 1978, Puckett and Montie reported a series of phallic reconstructions in which a groin flap was transferred by microvascular free-transfer techniques to the area of the penis. The phallus was insensible, but this represented the first free-flap reconstruction for phallic construction. In 1984, Chang and Hwang popularized use of the forearm flap. This flap has been modified by numerous individuals.
- We prefer to use an ulnar forearm flap with a combined Puckett modification of the flap and Biemer modification of the glans. These flaps allow sensible phallic construction that lets the patient stand to void and permits eventual prosthetic implantation because the phallus has both protective and erogenous sensibility.
- The techniques employed in transsexual patients are not different from techniques employed in trauma patients. The shapes of the skin paddles often must be tailored to the individual patient.

Surgical Anatomy of the Scrotum

Preoperative Preparation

Surgery of the Scrotal Wall

Vasectomy

Spermatocectomy and Surgery of the Epididymis

Hydrocelectomy

Surgical Treatment of Orchitis and Chronic Scrotal Pain

Surgery of the Seminal Vesicles

Management of Nonpalpable Testicular Lesions

The scrotum and its contents are unique body components because of their superficial anatomic location, which facilitates physical examination, imaging, and surgical access. Clinically, the external genitalia are one of the few organ systems in medicine that can have a significant psychosocial impact on a patient's well-being as well as their fertility potential. A significant reason that urologists must be thoroughly competent in dealing with conditions of the scrotum and scrotal contents is that physicians in other medical specialties are limited in their knowledge of scrotal anatomy, examination, disease entities, and treatment options. This unfamiliarity may seem perfunctory to most physicians, but it is of the utmost importance that urologists have a strong understanding of the anatomy, pathology, and surgical treatment of diseases that affect the external genitalia because of their significance in fertility potential and male endocrine function and impact on patient self-image.

SURGICAL ANATOMY OF THE SCROTUM

It is crucial to understand the blood supply to the organs within the scrotum when surgical intervention is indicated (Box 41-1). The availability of multiple blood supplies to the testis allows continued testicular viability when one or two of the arteries are compromised by injury or ligation. An understanding of scrotal anatomy readily permits accessibility for surgical procedures, including surgery of the scrotal wall, vasectomy, spermatocectomy, surgery of the epididymis, hydrocelectomy, and surgical treatment of orchitis and orchialgia.

Spread of Scrotal Infections and Postoperative Fluids Based on Scrotal Anatomy

There is a predictable pathway for the spread of scrotal infections including Fournier gangrene and necrotizing fasciitis of the scrotum and postoperative fluids based on scrotal anatomy. Anatomic barriers to the spread of necrotizing fasciitis include the dartos fascia of the penis and scrotum, Colles fascia of the perineum, and Scarpa fascia of the anterior abdominal wall. The testicles and epididymes are frequently spared in cases of necrotizing fasciitis of the scrotum (Figs. 41-1 and 41-2) (Gupta et al, 2007).

PREOPERATIVE PREPARATION

Anesthetic Technique for Scrotal Surgery

Effective anesthetic techniques for scrotal surgery range from local injection with or without sedation to spinal to general anesthesia. The use of a spermatic cord block with local infiltration of 0.5% lidocaine without epinephrine is a simple, cost-effective anesthetic technique that can be implemented by the surgeon for outpatient scrotal surgical procedures. Regional cord block typically can be performed without premedication with satisfactory patient analgesia (Wakefield and Elewa, 1994; Magoha, 1998). Spermatic cord block can be used in patients with large hydroceles for anesthesia by initially percutaneously draining the hydrocele, performing the block, and then performing hydrocelectomy (Reale et al, 1998). Outpatient scrotal surgery performed with midazolam sedation and a local block with sedation reversal at the end of the procedure has a very high patient satisfaction rate (Birch and Miller, 1994).

Preoperative Preparation and the Use of Antibiotics in Scrotal Surgery

The overall infection rate with scrotal surgery is relatively low, ranging from zero to 10%. There is no difference in the incidence of postoperative wound infections or complications in patients undergoing hydrocelectomy or spermatocectomy when comparing iodine-based versus chlorhexidine antiseptic preparations. Scrotal cases are considered as class II (clean-contaminated surgeries), which makes it reasonable to use preoperative antibiotics (Kiddoo et al, 2004). The American Urological Association (AUA) best practice policy statement on urologic surgery antimicrobial prophylaxis recommends a single dose of preoperative antibiotics if the patient has risk factors for infection, including advanced age, anatomic anomalies of the urinary tract, poor nutritional status, smoking, long-term corticosteroid use, immunodeficiency, externalized catheters, colonized endogenous or exogenous material, a distant coexistent infection, or prolonged hospitalization. The recommended antibiotic prophylaxis is a dose of a first-generation cephalosporin or clindamycin as an alternative antimicrobial (Wolf et al, 2008). Patients who underwent preoperative clipping for hair removal the morning of surgery had a significantly lower

Disorders of scrotal contents: orchitis, epididymitis, testicular torsion, torsion of the appendages, and Fournier's gangrene. In: Chapple CR, Steers WD, editors. Practical urology: essential principles and practice. London: Springer-Verlag; 2011.)

wound infection rate than patients who underwent shaving or clipping the night before surgery (Alexander et al, 1983).

SURGERY OF THE SCROTAL WALL

Cyst Excision

Patients with multiple scrotal cysts can be managed with surgical excision with excellent cosmetic results and low recurrence rates (Noël et al, 2006). The classic management of scrotal sebaceous cysts is surgical excision with excellent outcomes and minimal morbidity with good cosmetic results. Less invasive techniques, such as neodymium:yttrium-aluminum-garnet photocoagulation, have been performed successfully but are not considered standard management (Franco de Castro et al, 2002).

Partial and Total Scrotoectomy

Partial scrotoectomy is an uncommon procedure. Partial scrotoectomy is most commonly performed with infectious processes such as Fournier gangrene. Partial scrotoectomy has been advocated after

Figure 41-2. Sagittal view of anatomic barriers to the spread of infection. (Modified from Kavoussi PK, Costabile RA. Disorders of scrotal contents: orchitis, epididymitis, testicular torsion, torsion of the appendages, and Fournier's gangrene. In: Chapple CR, Steers WD, editors. Practical urology: essential principles and practice. London: Springer-Verlag; 2011.)

trans-scrotal exploration, orchiectomy, or biopsy or when aspiration has been performed for a scrotal mass and the pathology has revealed a nonseminomatous germ cell tumor of the testis. Prompt and aggressive management has resulted in no local recurrences secondary to scrotal tumor contamination, even when a tumor was found in the scrotoectomy specimen (Johnson and Babaian, 1980; Boileau and Steers, 1984; Leibovitch et al, 1995). There was no increase in local or distant recurrence in a small group that underwent aggressive local surgical resection and did not receive adjuvant chemotherapy (Giguere et al, 1988).

Total scrotoectomy is less commonly performed than partial scrotoectomy. Total scrotoectomy is often necessary when there is extensive involvement of the scrotum with Fournier gangrene. Total scrotoectomy also has been described for radical oncologic procedures, concomitantly with cystoprostatectomy, penectomy, or pelvic exenteration with aggressive cases of squamous cell carcinoma of the prostate (Sarma et al, 1991).

Debridement of the Scrotal Wall in Fournier Gangrene

Treatment of Fournier gangrene should include emergent radical surgical debridement and intravenous broad-spectrum antibiotics. When culture results are available, the antibiotics can be tailored to the organisms based on sensitivities. Treatment should be performed expeditiously and aggressively because Fournier gangrene is a life-threatening process. All nonviable and necrotic tissue must be aggressively excised (Fig. 41-3). An empirical broad-spectrum antibiotic regimen for the initial treatment of Fournier gangrene includes a third-generation cephalosporin, an aminoglycoside (if creatinine clearance is acceptable), and metronidazole (Hejase et al, 1996; Löfmark et al, 2010). Aggressive fluid resuscitation is required including the use of blood and blood products when needed. After debridement, adequate nutrition with early enteral feeding, when possible, is crucial for wound healing. Repeat debridement should be performed 2 days after the initial exploration to excise any remaining nonviable tissue. Multiple resections may be necessary. If the source of the infection is anorectal or the wound is contaminated, a colostomy may need to be

Figure 41-3. Aggressive debridement of Fournier gangrene. (From Kavoussi PK, Costabile RA. Disorders of scrotal contents: orchitis, epididymitis, testicular torsion, torsion of the appendages, and Fournier's gangrene. In: Chapple CR, Steers WD, editors. *Practical urology: essential principles and practice*. London: Springer-Verlag; 2011.)

performed to divert fecal flow (Ghnnam, 2008). Similarly, patients may require cystostomies for urinary diversion when there is a urinary source exacerbating the necrotizing fasciitis.

After the patient has been initially treated and resuscitated and all necrotic tissue has been excised, most wounds can be closed secondarily. Large wounds often require skin grafts for coverage. Fasciocutaneous rotational thigh flaps may be used for coverage with good cosmetic results (Bhatnagar et al, 2008). Wound closure is performed as soon as there is no evidence of infection or remaining necrotic tissue and there is a viable bed that will allow reapproximation or grafting (Ghnnam, 2008). In patients with less than 50% scrotal skin loss, primary closure most often can be performed without major difficulty. Rarely the testes may need to be placed in thigh pouches until the time of definitive reconstruction in cases with major scrotal skin loss (Gudaviciene and Milonas, 2008). Vacuum-assisted closure devices (Wound V.A.C.) have been used to help these complex wounds heal after wide excision and debridement. This technique has been shown to be as effective as conventional wound care in healing wounds. These patients require fewer dressing changes and have less pain, fewer skipped meals, and greater mobility (Ozturk et al, 2009). The use of a small intestinal submucosa graft and fibrin sealant is an option for closure of scrotal defects after excision for Fournier gangrene when standard grafting is impossible (Kavoussi and Bird, 2007).

A severity index was created and validated to identify prognostic factors in patients with Fournier gangrene. Parameters associated with mortality include abnormalities in heart rate, respiratory rate, serum creatinine, serum bicarbonate, serum lactate, and serum calcium. There is a 46% mortality rate in patients with a severity index score of 9 or greater and a 96% survival rate in patients with a severity index score of less than 9. Necrotizing fasciitis involving the abdominal wall or the lower extremities is associated with increased mortality (Corcoran et al, 2008).

Scrotoplasty for Other Benign Scrotal Conditions

Other nonmalignant conditions of the scrotum including hidradenitis suppurativa, postradiation lymphedema, and primary lymphangitis of the scrotum may require surgical excision. Depending on the extent and severity of the wound, different options exist for wound closure or coverage. Small lesions typically are excised and closed primarily, whereas larger wounds require split-thickness skin grafts or tissue flaps (Fig. 41-4) (Eswara and McDougal, 2013). In patients with hidradenitis suppurativa, disease recurrence has been shown to be related to disease severity and not to surgical method of reconstruction (Rompel and Petres, 2000). In patients with systemic disease (i.e., hidradenitis suppurativa, postradiation lymphedema), the surgeon and patient should be aware of potential recurrence; however, in this setting, recurrence is usually tolerated better than the initial lymphedema (Eswara and McDougal, 2013).

VASECTOMY

Vasectomy is a highly effective and safe form of contraception (Schwingl and Guess, 2000). Vasectomy was first described by Sir Ashley Cooper in the United Kingdom when he did experiments to vasectomize dogs (Cooper, 1827). Approximately 526,501 men undergo vasectomy annually in the United States, which makes vasectomy the most commonly performed urologic surgical procedure. Vasectomy is chosen as the method of contraception by 11% of married couples, and 0.01% of men between the ages of 25 and 49 undergo vasectomy annually (Barone et al, 2006).

Anesthetic Techniques for Vasectomy

Vasectomy can be performed under sedation, spinal, or general anesthesia, although most surgeons perform vasectomy under local anesthesia because most patients tolerate this method well, and it minimizes cost, anesthetic complications, and morbidity. The choice of local anesthetic is based on surgeon preference. Options for local anesthesia include 1% or 2% lidocaine without epinephrine or a 50/50 mixture of lidocaine and bupivacaine. The vas deferens is isolated through the scrotal skin and grasped tightly between the thumb and the middle finger of the nondominant hand in a superficial position just beneath the scrotal skin. A 25-gauge to 32-gauge needle is used to inject the local anesthetic subcutaneously to raise a small wheal over the vas deferens. After superficial anesthesia is achieved, the needle is carefully advanced into the vasal sheath, and a small amount of anesthetic is injected. Great care should be taken to use as few punctures as possible and as little needle movement as possible to minimize the risk of hematoma formation. EMLA (emulsion of lidocaine and prilocaine) cream applied as topical anesthesia on the scrotal skin 1 hour before injection of 1% lidocaine followed by vasectomy does not decrease the pain associated with vasectomy compared with the use of injectable anesthesia alone (Thomas et al, 2008).

The no-needle jet anesthetic technique has been described to eliminate the needle for anesthetic injection. This technique uses the MadaJet medical injector (Mada Medical Products, Carlstadt, NJ) to deliver lidocaine without epinephrine by means of a high-pressure injector through a tiny head to beneath the skin to diffuse a mist of anesthetic around the vas (Weiss and Li, 2005).

Conventional Technique

Vasectomy should be performed in a warm room with warm preparation solution to allow scrotal relaxation, regardless of the technique employed. Shaving should be done before the procedure to minimize the risk of infection. There is no difference in the rate of postvasectomy infection in men randomly assigned to prophylactic antibiotics versus no antibiotics; antibiotic prophylaxis is not recommended (Khan, 1978). In any chosen technique, the use of a single incision or bilateral scrotal incisions is based on surgeon preference. Many surgeons advocate bilateral scrotal

Figure 41-4. Wide excision of hidradenitis suppurativa of the perineum. **A, Before. B, After.** Use of excision and split-thickness skin graft for lymphedema of the penis and scrotum. **C, Before. D, After.**

incisions to minimize the risk of dividing the same side twice and to allow performing the vasectomy at a position in the midportion of the vas deferens. After induction of adequate local anesthesia, an incision is made over the isolated vas deferens, which is grasped tightly between the thumb and middle fingers. The vaginal sheath is sharply divided down to the vas. The vas is delivered through the incision; the deferential artery, nerves, veins, and adjacent tissue are separated from the vas, and the vas is divided. Some surgeons remove a small segment of vas deferens, although most urologists who perform vasectomy reversals prefer not to, which allows easier future reversal. The AUA Guideline ([American Urological Association, 2012](#)) states that removal of a segment of vas deferens for histologic confirmation is neither required nor recommended. Most surgeons occlude the testicular and abdominal ends of the vas with suture ligation, hemoclips, intraluminal fulguration with electrocautery, or fascial interposition. These techniques are discussed further later on. The same procedure is repeated on the contralateral vas deferens.

“No-Scalpel” Technique

No-scalpel vasectomy was initially described in China in 1974 ([Li, 1976](#)). Routine antibiotics are not needed for patients undergoing no-scalpel vasectomy with sterile technique ([Seenu and Hafiz, 2005](#)). **The no-scalpel technique significantly decreases the rate of hematomas, infections, and pain during the procedure.** Patients who undergo the no-scalpel technique also resume sexual activity sooner after surgery and have a shorter operative time than

occurs with the conventional technique ([Sokal et al, 1999](#); [Cook et al, 2007a](#)).

The vas and perivascular tissue are firmly secured through the skin with a ring-tipped vas deferens fixation clamp ([Fig. 41-5](#)) after local anesthesia has been administered as described earlier ([Fig. 41-6](#)). A modified, sharpened tipped curved hemostat ([Fig. 41-7](#)) is used to puncture the skin and the vas sheath, and the hemostat is spread to stretch the hole that is made. The vas is pierced with one tip of the hemostat and lifted through the skin opening. The vas is regripped with the ring clamp, and the hemostat is used to dissect the posterior perivascular tissue. The vas deferens is divided, the occlusion technique of choice is employed, inspection is done for hemostasis, and the vas deferens is replaced in the scrotum. The same procedure is performed on the contralateral vas deferens ([Huber, 1988](#)). The perforation in the skin can be closed with an absorbable suture, but it can also be left open and heals well without closure.

Minimally Invasive Vasectomy

There are several variations to the technique of the no-scalpel vasectomy; however, if there is any variation in the steps or specific instruments, the vasectomy should be called minimally invasive vasectomy rather than no-scalpel vasectomy technique. One variation of this technique employs local anesthesia; fixes the vas through the scrotal skin with the ring-tipped vas deferens fixation clamp; and pierces the scrotal skin, vas sheath, and vas deferens in the midline with a sharpened tipped curved hemostat held at 45 degrees from horizontal ([Fig. 41-8](#)). To prepare the vas deferens for division,

Figure 41-5. Ring-tipped vas deferens fixation clamp. The cantilevered design prevents injury. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

Figure 41-6. Vas fixed in the ring clamp. The scrotal skin is tightly stretched over the most prominent portion of the vas. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

the clamp is rotated 180 degrees relative to the pierced vas deferens. The remainder of the procedure is performed in the same manner as described earlier, and this is done bilaterally (Schlegel and Goldstein, 1992).

Another technique for performing minimally invasive vasectomy is to isolate the vas deferens after induction of adequate local anesthesia, grasp it tightly between the thumb and middle finger, and puncture the skin overlying the vas deferens with a sharpened tipped curved hemostat. The curved hemostat is used to spread the skin to enlarge the vertical slit in the skin just large enough to allow the ring-tipped vas deferens fixation clamp to fit through to grasp the vas deferens. The vas deferens is grasped and brought up through

Figure 41-7. Sharp, curved mosquito hemostat. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

Figure 41-8. Puncture of the skin, vas sheath, and wall into the lumen. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

the puncture, and the vaginal fascia and vessels can be spread off the vas deferens to expose the bare vas deferens by spreading the sharp-tipped curved hemostat onto the vaginal fascia to open the vaginal fascia (Figs. 41-9 and 41-10). The remainder of the vasectomy is performed as described earlier for bilateral procedure (Li et al, 1991). This modification of making the puncture before grasping the vas deferens with the ring-tipped vas deferens fixation clamp was found to decrease the operative time significantly and showed no difference in incision length, postoperative pain, or time to return to work in a randomized prospective evaluation (Chen et al, 2005).

Methods of Vasa Obstruction and Male Sterilization

Numerous vasectomy occlusion techniques are employed, including excision and ligation, thermal occlusion with intraluminal electrocautery, mechanical occlusion with hemoclips, fascial interposition, and chemical occlusion with percutaneous techniques. There have been concerns about the risk of vasa necrosis

Figure 41-9. Delivery of the clean vas. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

Figure 41-10. Segment cleaned. (From Li S, Goldstein M, Zhu J, et al. The no-scalpel vasectomy. *J Urol* 1991;145:341–4.)

and sloughing distal to the ligated end when suture ligation is performed, theoretically increasing the risk of recanalization. Low-voltage thermal occlusion with intraluminal electrocautery in the abdominal and testicular ends of the divided vas deferens reduces recanalization rates to less than 0.5% (Schmidt, 1987; Barone et al, 2004). Vasectomy failure rates have been reported to be less than 1% when the testicular and abdominal ends of the divided vas deferens are occluded with hemoclips (Moss, 1974; Bennett, 1976). Interposition of dartos fascia between the divided ends of the vas deferens is another technique for occlusion. This method has been reported to reduce the recanalization rate even further, to nearly zero (Esho and Cass, 1978; Sokal et al, 2004).

Percutaneous vasectomy has been performed on more than 500,000 men in China. This technique employs chemical occlusion

by fixing the vas deferens up to the scrotal skin tightly, puncturing the lumen of the vas deferens with a 22-gauge needle, and cannulating the lumen of the vas deferens with a 24-gauge blunt needle. For confirmation of vas deferens cannulation, Congo red is injected into the lumen of the abdominal end of the right vas deferens, and methylene blue is injected into the lumen of the left vas deferens before chemical occlusion by injection of 20 μ L of 2 parts phenol to 1 part *N*-butylcyanoacrylate mixture. Following chemical occlusion, the patient should void. If the urine is red, the left side was not cannulated, if it is blue, the right side was not cannulated, and if it is brown, that indicates bilateral successful cannulation (Ban, 1980; Li, 1980). Although these chemicals are not approved for use in the United States by the Food and Drug Administration, they appear to be safe based on toxicologic testing and experience in China.

Fascial interposition has been found to decrease vasectomy recanalization rates the most significantly. Randomized controlled trials examining the other techniques are unavailable. Several trials have been performed using irrigation of the abdominal ends of the vas deferens with saline, but there was no difference in time to azoospermia (Cook et al, 2007b).

Open-ended vasectomy, in which the testicular portion of the vas deferens remains patent, is another technique that has been evaluated with the aim of decreasing epididymal pressure by performing intraluminal cautery or another method of occlusion on the abdominal end, while leaving the testicular end unoccluded. Sperm granulomas develop in 97% of patients undergoing open-ended vasectomy. The granulomas are thought to reduce pressure-induced damage to the epididymis, but they increase the vasectomy failure rate to 7% to 50% (Shapiro and Silber, 1979; Goldstein, 1983). There is a significant decrease in the failure rate with open-ended vasectomy when fascial interposition is performed (decreasing the failure rate by approximately 7%) (Li et al, 1994).

Performing Vasectomy to Make Microscopic Vasectomy Reversal Easier

Technical aspects of performing vasectomy can affect the ease of microsurgical vasectomy reversal in the future if needed (Mammen et al, 2008). One procedural aspect is that excising a lengthy (>1 cm) segment of vas deferens is associated with the need for a higher scrotal incision, possibly up to the lower inguinal region, with the potential for anastomotic tension with microscopic vasectomy reversal. Vasectomy reversal can be far more difficult when a lengthy portion of the vas deferens has been excised, with concomitant increases in operative time, length of incision, and postoperative pain (Practice Committee of the American Society for Reproductive Medicine, 2006).

Another procedural aspect is the location along the length of the vas deferens where the vasectomy is performed. Experts in microsurgery agree that the anastomosis is least problematic when the lumen of the vas deferens is largest and most concentric, as opposed to the lumen in the epididymis or the convoluted vas (Mammen et al, 2008). Prospective studies show that the length of the testicular vas deferens present at the time of reversal has a direct correlation with the presence of seminal fluid containing intact sperm at the time of microscopic vasectomy reversal. A testicular length of vas deferens less than 2.7 cm correlates with seminal fluid without intact sperm 85% of the time, and testicular length more than 2.7 cm is associated with intact sperm in seminal fluid 94% of the time. For each 1-cm increase in testicular remnant length, the probability of whole sperm being present increases fourfold (Witt et al, 1994). Division of the vas deferens should be performed approximately 3 cm distal to the cauda of the epididymis in the straight portion of the vas deferens at the time of vasectomy.

The other technical aspect to consider is the occlusion technique employed. All occlusive modalities for vasectomy carry a similarly high efficacy in terms of postprocedure azoospermia. To date, no specific studies on occlusion technique as a predictor of reversal success have been performed. A simple transection of the vas

deferens followed by low-voltage intraluminal cautery occlusion and then fascial interposition provides successful vasectomy and may result in minimal inflammatory reaction. Minimizing inflammation near the vas deferens would provide the optimum condition for microscopic vasectomy reversal in the future (Mammen et al, 2008).

Postoperative Care and Follow-Up Semen Analysis

Routine postoperative care practices vary but typically include the use of ice packs on the scrotum intermittently for the first 48 hours, limited heavy or strenuous activity for 1 week, and the use of nonsteroidal anti-inflammatory drugs as needed for pain if the patient does not have any contraindications to these medications. There is no vasectomy technique that is 100% effective. Time to reach azoospermia is variable, although greater than 80% of patients achieve azoospermia by 3 months and after 20 ejaculations. The AUA Vasectomy Guideline (American Urological Association, 2012) recommends checking the first postvasectomy semen analysis 8 to 16 weeks after vasectomy. Persistent nonmotile sperm are present in 1.4% of patients after vasectomy. These data point to obtaining a semen analysis at 3 months and 20 ejaculations after vasectomy to reveal azoospermia. If the semen analysis does not show azoospermia, periodic semen analyses can be obtained every 6 to 12 weeks until azoospermia is achieved. Additional samples should be submitted if the initial semen analysis has motile sperm or greater than 100,000 nonmotile sperm/mL. Patients who have small numbers of persistent nonmotile sperm can be advised cautiously to discontinue contraception (Griffin et al, 2005). There is evidence that these men ultimately reach azoospermia. Vasectomy should be repeated if any motile sperm are seen in the ejaculate 6 months after the initial vasectomy (American Urological Association, 2012).

An immunodiagnostic test, the SpermCheck Vasectomy (ContraVac, Charlottesville, VA), has been developed to allow patients to test themselves for severe oligospermia or azoospermia at home after vasectomy. This test was developed to increase compliance with postvasectomy evaluation of semen parameters. The SpermCheck Vasectomy test was 96% accurate at predicting whether sperm counts were greater or less than a threshold of 250,000 sperm/mL (Klotz et al, 2008).

Local and Postoperative Complications

The rates of surgical complications after vasectomy are approximately 1% to 2%. Local complications of vasectomy include hematoma, infection, Fournier gangrene, chronic scrotal pain, and traumatic fistula/scrotal sinus (Awsare et al, 2005). The most important predictor of postoperative complications is surgeon volume and experience (Kendrick et al, 1987).

Hematoma is the most common complication of vasectomy. The rate of hematoma formation after vasectomy ranges from 0.09% to 29%, with a mean incidence of 2% (Kendrick et al, 1987). The no-scalpel technique has decreased the hematoma rate to a 0.5% incidence (Pant et al, 2007).

The rate of infection from vasectomy with the conventional technique was reported to be between 12% and 38% but decreased to 0.4% with the no-scalpel technique (Appell and Evans, 1980; Pant et al, 2007). Although exceedingly rare, Fournier gangrene has been reported as a complication in men undergoing vasectomy (de Diego Rodríguez et al, 2000; Romero Pérez et al, 2004).

Short-term scrotal pain lasting a few weeks can occur in 30% of men. The medical literature on postvasectomy pain syndrome, or long-term scrotal pain after surgery, consists of studies with small sample sizes, nonvalidated pain measures, high nonresponse rates, and variable outcome measures. The most robust study identified the incidence of chronic scrotal pain severe enough to seek medical attention to be 0.9% (Leslie et al, 2007), although it has been reported to be as high as 15% (McConaghy et al, 1996). Postvasectomy pain syndrome has no association with immediate postoperative complications such as hematoma or infec-

tion. There are several theories about the cause of postvasectomy pain syndrome. One is that dilation of the epididymal duct with obstruction of the testicular end of the vas deferens produces interstitial fibrosis. Another theory is that extravasation of spermatozoa, with epididymal duct rupture forming a sperm granuloma at the site where the vas deferens is transected, results in perineural fibrosis and inflammation because sperm are highly antigenic (McMahon et al, 1992). This theory contradicts the previous belief that sperm granulomas are protective against postvasectomy pain syndrome by relieving pressure, although most sperm granulomas are asymptomatic (Tandon and Sabanegh, 2008). There are markedly increased pressures in the epididymis and the testicular end of the vas deferens after vasectomy, but these pressures were not found to be transmitted to the seminiferous tubules in human micropuncture studies (Johnson and Howards, 1975). It is unclear why some patients develop long-term symptoms and others develop transient symptoms. Factors such as age, socioeconomic status, race, environment, and vasectomy technique have not identified patients at risk for postvasectomy pain syndrome (Tandon and Sabanegh, 2008).

Conservative therapy should be the first-line therapy and includes scrotal elevation and support, heat or ice (as needed for comfort), and nonsteroidal anti-inflammatory drugs. Empirical antibiotic therapy is not recommended without evidence of infection (Selikowitz and Schned, 1985). Conservative therapy should be employed for at least 3 months for postvasectomy pain. Spermatic cord blocks and pain management techniques should be considered after failure of conservative therapy.

Surgical therapy might be considered on an individualized basis if the aforementioned methods fail. When pain is clearly localized to a sperm granuloma, excision of the granuloma and intraluminal cautery occlusion of the vas deferens may relieve the pain and prevent recurrence (Schmidt, 1979). Epididymectomy has been performed in patients who had point tenderness to the epididymis and epididymal dilation after vasectomy and failed conservative therapy. Predictors of poor outcomes with epididymectomy are atypical symptoms, concomitant erectile dysfunction, and a normal-appearing epididymis on scrotal ultrasonography (West et al, 2000). Of patients who were properly selected for epididymectomy, 50% were cured of postvasectomy pain syndrome (Chen and Ball, 1991). The patient must consider that vasectomy reversal will no longer be feasible after epididymectomy. Vasectomy reversal rendered 69% of patients with postvasectomy pain syndrome pain-free (Nangia et al, 2000). Although it has been evaluated in only a small number of patients, microscopic denervation of the spermatic cord in patients who failed conservative treatment resulted in complete pain relief in 76% of these men (Ahmed et al, 1997). The last resort consideration after failure of conservative and more invasive interventions have failed is orchiectomy for severe intractable pain after vasectomy. Pain relief was reported in 73% of men who underwent inguinal orchiectomy versus 55% of men who underwent scrotal orchiectomy for postvasectomy pain syndrome (Davis et al, 1990). There is a report of 0.3% rate of scrotal sinus/vasocutaneous fistula after no-scalpel vasectomy (Pant et al, 2007).

Association of Vasectomy with Long-Term Systemic Disease

Previous studies found an increased risk of prostate cancer in men who underwent vasectomy (Giovannucci et al, 1993). Detection bias is thought to be the source of this association of prostate cancer with vasectomy (Millard, 1999). More recent investigations have found that there is no association between vasectomy and prostate cancer (Schuman et al, 1993; Holt et al, 2008). There is no association between vasectomy and prostate cancer in developing countries in which there are low incidences of prostate cancer in the general population as well (Schwingl et al, 2009). Screening recommendations for prostate cancer should be no different in men who have undergone vasectomy than in men who have not undergone vasectomy (Healy, 1993).

Vasectomy does not place the patient at an increased long-term risk for cardiovascular disease or atherosclerosis (Coady et al, 2002; Goldacre et al, 2005). Previous studies suggested that vasectomy may be a risk factor for patients with primary progressive aphasia, a dementia syndrome with aphasia as the presenting symptom (Weintraub et al, 2006). There are no longitudinal studies confirming this association, and there have been many large, epidemiologic studies comparing men with and without vasectomy that have not shown any increased risk of dementia. There is no evidence that vasectomy adversely affects psychological health status (Thonneau and D'Isle, 1990).

Antisperm Antibodies

There is a disruption of the blood-testis barrier when vasectomy is performed. Of men who undergo vasectomy, 60% to 80% have detectable levels of antisperm antibodies in the serum (Fuchs and Alexander, 1983). After vasectomy, 50% to 60% of men develop sperm agglutinating antibodies, and 20% to 30% develop sperm immobilizing antibodies (Kovacs and Frances, 1983). Although some studies suggest that antisperm antibodies persist, others suggest that they diminish 2 or more years after vasectomy, but neither immune complex deposition nor circulation is increased in men who have undergone vasectomy (Witkin et al, 1982).

KEY POINTS: VASECTOMY

- No vasectomy technique is 100% effective.
- Patients can be advised to initiate unprotected intercourse following a semen analysis obtained 8 to 16 weeks after vasectomy that demonstrates azoospermia or rare nonmotile sperm.
- The no-scalpel technique significantly decreases the rate of hematomas, infections, and pain during the procedure.
- Fascial interposition is the occlusion technique that has been found to decrease vasectomy failure rates the most significantly.
- Technical aspects of performing vasectomy can affect the ease of microsurgical vasectomy reversal in the future if needed.
- There is no association between vasectomy and prostate cancer or cardiovascular disease.

SPERMATOCECTOMY AND SURGERY OF THE EPIDIDYMIS

Surgical Indications

A spermatocele or epididymal cyst is a cystic dilation of an epididymal tubule that is benign in nature. Spermatoceles are common and are found incidentally on high-resolution ultrasonography in 30% of men. They are typically asymptomatic and do not cause epididymal obstruction, and they rarely require intervention. Men typically seek surgical treatment when the spermatocele has reached the approximate size of the testis and is causing pain with point tenderness (Walsh et al, 2007).

Surgical treatment for chronic epididymitis is poorly studied in clinical trials with no level 1 evidence to support the use of a specific surgical procedure. In one study, 10 patients with chronic epididymitis (defined as epididymal pain lasting >3 months) underwent epididymectomy for intractable symptoms. Only one of these patients had significant improvement in pain (Davis et al, 1990). Other authors reported much higher success rates, such as six out of seven patients (86%) having significant improvement in pain after epididymectomy (Chen and Ball, 1991). Chronic or recurrent epididymitis and persistent epididymalgia with point tenderness to the epididymis may be reasonable indications for epididymectomy (Padmore et al, 1996).

Surgical treatment for chronic epididymitis should be considered only after failure of extensive conservative therapy and after appropriate counseling, with the understanding that the symptoms may not improve after surgery or may worsen. A retrospective review of men who underwent epididymectomy for chronic epididymitis showed that outcomes were best when the patient had a palpable epididymal abnormality on physical examination. Men in this study without a palpable abnormality but with ultrasound changes had slightly worse outcomes, and men with neither a palpable abnormality nor a demonstrable abnormality on ultrasonography did not improve with epididymectomy (Calleary et al, 2009).

Purulent epididymitis diagnosed by a combination of physical examination, ultrasound evaluation, and occasionally needle aspiration of the epididymis is an absolute indication for epididymectomy (Arbuliev et al, 2008). Epididymectomy is also the treatment of choice for epididymal abscesses and chronic infectious epididymitis that is unresponsive to antibiotic treatment. Diagnostic epididymal puncture and aspiration should not be performed in men with interest in future fertility because this procedure would result in epididymal obstruction. Total epididymectomy may relieve chronic persistent pain localized to the epididymis after vasectomy.

Epididymal malignancies are extremely rare, and 73% of nontransilluminating, solid epididymal masses are benign adenomatoid tumors (Beccia et al, 1976). Surgical extirpation should be considered for adenomatoid tumors, especially if there is any suspicion for malignancy (Alvarez Maestro et al, 2009).

Partial and Total Epididymectomy

Any patient undergoing epididymal surgery should be counseled extensively that the surgery may impair his fertility or cause sterility if bilateral epididymal surgery is required because the distal epididymis consists of a single tubule. Partial or total epididymectomy can be approached scrotally through a median raphe or a unilateral transverse scrotal incision to deliver the testis. The vas deferens is identified, isolated, ligated, and divided. The testicular end of the vas deferens is followed to the vasoepididymal junction. The tunica vaginalis is opened, and the plane of dissection between the epididymis and the testis is found to divide the epididymis from the testis. Great care should be taken to avoid injury to the spermatic cord and testicular artery. The efferent ducts superior to the testicular vasculature are ligated with an absorbable suture to complete the epididymectomy. The edges of the tunica vaginalis where the epididymis was excised are approximated with a running absorbable suture, which helps with hemostasis. The dartos fascia and skin are closed in layers with absorbable suture. In the case of partial epididymectomy, ligations are performed between the testis and epididymis with absorbable suture to excise the affected portion of the epididymis, while leaving the remainder attached to the testis with its vascular supply intact (Figs. 41-11 and 41-12).

Spermatocelectomy and Excision of Epididymal Cysts

Spermatocelectomy can be approached scrotally through a median raphe or a unilateral transverse scrotal incision to deliver the testis. The tunica vaginalis is opened, and the spermatocele is identified and dissected free from the epididymis. The epididymal-spermatocele attachment is ligated and divided to complete the spermatocelectomy. The tunica vaginalis is closed, and the dartos fascia and scrotal skin are reapproximated in layers.

Excision of Epididymal Tumors

As discussed earlier, most epididymal nontransilluminating masses are benign adenomatoid tumors. Fine-needle aspiration of solid epididymal masses has been evaluated and found to be very accurate compared with surgical pathology (Gupta et al, 2006). When malignancy is suspected, an inguinal approach should be used with clamping of the spermatic cord and delivery of the testis. The addition of testicular hypothermia by adding ice slush to the

Chevassu maneuver (of clamping the vessels) was employed and found to salvage three of five testicles with benign processes after clamping and parenchymal biopsy (Goldstein and Waterhouse, 1983). When malignancy is ruled out, the epididymal mass may be excised as for a spermatocelectomy.

Complications

Complications of epididymectomy, spermatocelectomy, and excision of epididymal masses are rare. Complications include bleeding, infection, damage to the testicular artery with resultant testicular atrophy, and recurrence in cases of spermatocelectomy (Kiddoo et al, 2004; Zahalsky et al, 2004). Complications also include impairment of fertility with obstruction of the epididymal tubules and possible sterility in bilateral cases, necessitating counseling and recommending sperm cryopreservation in men who undergo bilateral procedures and have an interest in fertility. Approximately 17% of patients undergoing spermatocelectomy have resultant epididymal injury (Zahalsky et al, 2004). The overall complication rate has been reported to be 20%, with the most common complications being persistent scrotal pain and infection. Leaving a scrotal drain did not decrease complication rates (Kiddoo et al, 2004).

HYDROCELECTOMY

Hydrocele in an adult is caused by excessive fluid secretion by the visceral tunica albuginea without adequate reabsorption of this fluid by the parietal peritoneum around the testis.

Inguinal Surgical Approach

Men in whom hydroceles have been diagnosed, in which there is suspicion for concomitant malignancy, should undergo high-resolution scrotal ultrasonography. If malignancy is suspected, an inguinal approach should be used to allow control of the spermatic cord in preparation for radical orchiectomy. If this approach is taken and no malignancy is encountered, the testis can be spared and the hydrocele can be repaired by one of the techniques described subsequently.

Scrotal Surgical Approaches

When there is no evidence of malignancy on physical examination and high-resolution ultrasonography, hydroceles may be approached scrotally through a median raphe or a transverse unilateral incision. In all techniques, the hydrocele is dissected and delivered intact to allow the easiest dissection. After the hydrocele is delivered, an opening in the sac is made away from the testis, epididymis, and cord structures, and the fluid is suctioned out. The hydrocele sac is opened further to expose the sac for the elected repair. The overall single-treatment success rates for surgical hydrocelectomy are between 90% and 100% (Rodriguez et al, 1981).

Excisional techniques are the least likely to result in recurrence of a hydrocele. Excising the hydrocele is recommended for large, long-standing, thick-walled, loculated hydroceles. The hydrocele sac is opened, taking great care not to injure the spermatic cord, and the sac is simply excised, leaving room to oversew the edge of the excised sac without endangering the cord or the epididymis. A 3-0 chromic suture can be used in a baseball-stitch manner to oversew the edge of the sac (Fig. 41-13).

The Jaboulay bottleneck technique (1902) is a useful method for large, floppy, thin hydrocele sacs. This technique is performed by excising the sac as described previously, but a larger margin of excision should be left between the edge of the sac and the testis and epididymis to allow for sewing the edges of the sac together behind the cord, without compressing the cord (Fig. 41-14).

If there appears to be a risk for hematoma after excision and oversewing with either technique, a Penrose drain can be left in the dependent portion of the scrotum and fixed in place to the scrotum. The dartos fascia and skin are then closed in layers. Fluffs and a scrotal support are used for the dressing.

Figure 41-12. A and B, Entire vasoepididymal complex is dissected to the caput.

Figure 41-13. Simple excision of the thick-walled hydrocele sac and oversewn edges.

Figure 41-15. Lord plication technique.

Figure 41-14. Jaboulay bottleneck technique for excision of thin, floppy sacs.

Plication techniques are suitable for smaller, thin-walled hydroceles but should not be used in large, long-standing, thick-walled, multiloculated hydroceles because this leaves a large bundle of plicated tissue in the scrotum. The **Lord plication technique** (1964) is performed by opening the hydrocele as described earlier, delivering the testis, cauterizing or oversewing the cut edges of the sac, and using interrupted, radially placed chromic sutures to plicate the sac. Closure is performed as described earlier. Drains are unnecessary with plications (Fig. 41-15).

A minimally invasive technique can be used by making a 2-cm incision in the scrotum. The hydrocele is drained, followed by excision of a portion of parietal tunica vaginalis. The tunica vaginalis is everted, sutured to the subcutaneous tissue, and a surgical drain is placed (Saber, 2011).

Sclerotherapy

Sclerotherapy is another treatment option with a single-treatment success rate ranging from 33% to 75% (Levine and Dewolf, 1988).

TABLE 41-1 Hydrocelectomy Techniques and Risks

	RECURRENCE	HEMATOMA
Excision	Decreased	Increased
Plication	Increased	Decreased

This option may be a good choice for patients who cannot tolerate anesthesia or who refuse surgical treatment. The common steps of the procedure include needle aspiration of the hydrocele fluid, followed by injection of local anesthesia, and ultimately instillation of the sclerosing agent. The most commonly used sclerosing agent is tetracycline, although 2.5% phenol solutions, 95% alcohol, and ethanolamine oleate also have been used effectively (Nash, 1984; Hellström et al, 1986; Miskowiak and Christensen, 1988). One study showed no statistically significant improvement in patients who underwent aspiration of hydrocele fluid alone versus aspiration plus instillation of tetracycline as a sclerosing agent, with a higher complication rate in the sclerotherapy group (Breda et al, 1992). When sclerotherapy was compared with hydrocelectomy, the success rate was higher in hydrocelectomy, although the hydrocelectomy group had a higher complication rate. Nonetheless, the patients who underwent hydrocelectomy had higher satisfaction rates (Beiko et al, 2003).

Complications

The most common complication after hydrocelectomy is hematoma (Table 41-1). The overall complication rate in hydrocelectomy is approximately 19%, including hematoma, infection, persistent swelling, recurrence, injury to spermatic vessels, and chronic pain. Although the use of a drain in selected patients is recommended, it has not been proven so far to decrease complication rates (Kiddoo et al, 2004). When repairing large hydroceles, great care must be taken not to injure the epididymis and spermatic vessels because they may be splayed within the hydrocele layers.

Injury to the epididymis or vas deferens can put the patient's future fertility at risk (Zahalsky et al, 2004).

Sclerotherapy complications include scrotal pain in 29% to 55% of patients (Rencken et al, 1990; Ovrebø and Vaage, 1991), recurrence, hematoma, and infection; febrile chemical epididymo-orchitis has also been reported with sclerotherapy (López Laur and Parisi, 1989; Beiko et al, 2003). Sclerotherapy can have an adverse effect on fertility and should be avoided in patients interested in maintaining fertility (Sigurdsson et al, 1994).

SURGICAL TREATMENT OF ORCHITIS AND CHRONIC SCROTAL PAIN

Orchitis is defined as inflammation of the testicle (Delavierre, 2003). Typical symptoms of orchitis include scrotal pain, swelling, tenderness, and skin fixation over the testicle. The Prehn sign has been described in orchitis and epididymitis when there is relief of pain with elevation of the testicle over the symphysis pubis (Noske et al, 1998). The Prehn sign is nonspecific and nondiagnostic and does not distinguish epididymo-orchitis from spermatic cord torsion. Orchitis can cause an irreversible effect on spermatogenesis, affecting the quality and number of spermatozoa. Lymphocytic infiltration and seminiferous tubule damage are seen on testicular biopsy specimens of subfertile men with a history of chronic orchitis (Schuppe et al, 2008).

Chronic orchialgia is defined as constant or intermittent scrotal pain lasting at least 3 months or longer and with an unclear cause (Costabile et al, 1991). In patients with clinical orchialgia, a scrotal ultrasound scan should be obtained because testicular malignancy has been reported to masquerade as orchialgia (Vaidyanathan et al, 2008). At least 10% of men with testicular malignancy initially receive an incorrect diagnosis of an acute inflammatory process or spermatic cord torsion (Cook and Dewbury, 2000). High-frequency transducer ultrasonography (7.5 to 10 MHz) is considered the best modality for evaluation of scrotal pathology including orchitis (Lee et al, 2008).

Although there is no level 1 evidence for the optimal treatment of chronic orchialgia or epididymitis, local supportive therapy, including heat, nerve blocks, analgesics, tricyclic antidepressants, anticonvulsants (e.g., gabapentin), and anti-inflammatory drugs, is commonly applied and may offer some relief (Davis and Noble, 1992). Other treatment options implemented for chronic epididymitis include phytotherapy, anxiolytics, narcotics, acupuncture, and steroid injection therapy (Nickel et al, 2002). Despite evidence that 75% of patients do not have an identifiable bacterial urinary tract infection concomitantly with clinical epididymitis, antibiotics are routinely given. Empirical antibiotic administration in the absence of positive urine cultures has been steadily increasing, from 75% to 95% between the years of 1965 and 2005. Antibiotic administration does not decrease the length of symptoms or the return to full activity in men without an identifiable bacterial pathogen (Mittmeier et al, 1966).

Orchiectomy

Surgical treatment for chronic orchialgia is poorly studied in clinical trials, with no level 1 evidence to support the use of a specific surgical procedure. In the available literature, fewer than 250 patients with chronic scrotal pain have been treated with differing surgical therapies despite the common nature of chronic scrotal pain. There is no level 1 evidence that orchiectomy is effective for the treatment of chronic orchialgia. If orchiectomy is recommended, the patient should have failed previous conservative therapy and must be apprised of the risks, benefits, and options of orchiectomy. Because many patients continue to have pain or have pain recur after orchiectomy, the surgeon should be aware of the medicolegal aspects of this action. If orchiectomy is performed, it should be performed through an inguinal incision because this approach has been shown to have a better outcome than the scrotal approach for orchialgia (Davis and Noble, 1992).

Microsurgical Denervation of the Spermatic Cord

Some surgeons have attempted microsurgical denervation of the spermatic cord for symptomatic relief of chronic scrotal pain. Microsurgical denervation of the spermatic cord was performed in 79 men on 95 testicular units for chronic orchialgia over a mean duration of 62 months. There was complete relief of pain in 71% of the patients, partial relief of pain in 17%, and no change from the preoperative status in 12%, with no patients experiencing worsened postoperative pain. The mean follow-up time was 20.3 months (Strom and Levine, 2008). Microscopic denervation has been shown to be beneficial if the patient has temporary relief of orchialgia with a spermatic cord block (Levine et al, 1996; Benson et al, 2013). Spermatic cord denervation has been shown to be successful in men who underwent alternative surgical procedures to treat chronic orchialgia (i.e., epididymectomy, varicocelectomy) (Larsen et al, 2013).

To mobilize the spermatic cord, microsurgical denervation is performed by the same approach as microscopic subinguinal ligation of the spermatic veins for varicocele repair. Microscopic transection of all branches of the genitofemoral nerve along the spermatic cord is performed, while preserving the testicular artery, the vas deferens, the vasal vessels, and some of the lymphatics (Fig. 41-16). This procedure also can be performed laparoscopically (Cadeddu et al, 1999). If fertility is not a concern, it is recommended to divide the vas deferens as well to eliminate sympathetic innervation, which may contribute to orchialgia by a sympathetic dystrophy component (Levine et al, 1996).

Large, clinically palpable varicoceles can cause orchialgia. The pain typically improves with the patient in the supine position because the varicocele decompresses. In a small series of men who underwent microscopic varicocelectomy for clinically palpable varicoceles with concomitant orchialgia, slightly more than 50% had resolution of pain, and 90% had improvement (Chawla et al, 2005). Higher success rates were reported in a previous, larger powered, retrospective study (Peterson et al, 1998). Smaller, non-clinical varicoceles are unlikely to cause orchialgia and should be managed conservatively.

Retractile testes are another source of scrotal pain in men. A careful history must be elicited to make this diagnosis because the patient may not demonstrate a retractile testis on examination. The history is consistent with orchialgia only when the testis retracts up toward the external inguinal ring. This is typically seen in younger men with hyperactive cremasteric reflexes. Orchiopexy can be performed in these patients as it would in patients with intermittent torsion (Forte et al, 2003). When orchiopexy is offered, it should be performed by a dartos pouch technique to prevent

Figure 41-16. Microsurgical denervation. The goal is to transect all branches of the genitofemoral nerve while preserving the vas deferens, vasal vessels, testicular artery, and lymphatics.

retraction, as is recommended for testicular torsion (Redman and Barthold, 1995).

The other surgical treatment for orchialgia secondary to the retractile testis is to perform microscopic release of the cremasteric muscle. This technique is performed in a similar manner to microscopic subinguinal varicocelectomy. The spermatic cord is mobilized and isolated, and the cremasteric muscle is divided circumferentially, while preserving the vasculature of the spermatic cord and the vas deferens. This technique effectively releases the spermatic cord, not allowing retraction of the testis with hypercontraction of the cremasteric muscles.

KEY POINTS: SURGERY OF THE SCROTAL CONTENTS

- Patients undergoing epididymal surgery should be counseled that the surgery may impair their fertility or cause sterility if bilateral epididymal surgery is required.
- Sclerotherapy as treatment for a hydrocele can have an adverse effect on fertility and should be avoided in patients interested in maintaining fertility.
- Antibiotics should not be given for epididymitis or orchitis without evidence of infection.
- Patients with chronic orchialgia should receive a scrotal ultrasound scan.
- When a clinically palpable varicocele is encountered in a patient with orchialgia, varicocelectomy resolves the pain 50% of the time.

SURGERY OF THE SEMINAL VESICLES

In 1561, Gabriele Fallopius, a renowned Italian anatomist and physician, first described the seminal vesicles as paired male organs. He was considered an authority in the field of sexuality and advocated the use of condoms to decrease the transmission of syphilis. There was a great deal of interest in the seminal vesicles in the late 19th century because of their discovered involvement with inflammatory diseases (Brewster, 1985).

Seminal vesicle secretions contribute 50% to 80% of the volume of the ejaculate. The pH of the secreted fluid is neutral to slightly alkaline, and the mean volume is approximately 2.5 mL. The secreted fluid contains fructose and other carbohydrates necessary for sperm motility. It also contains a coagulation factor and prostaglandins A, B, E, and F (Tauber et al, 1975).

Primary disease processes of the seminal vesicles are very rare, although secondary processes are seen more commonly. Diagnosis of such entities has improved over the years with advanced imaging, particularly magnetic resonance imaging (MRI) (Kim et al, 2009; Chiang et al, 2013). Because of the anatomic location, surgical access and management of seminal vesicle pathology can be difficult for the urologist.

Anatomy

The seminal vesicles are paired male organs with no equivalent in the female. It is useful to understand the developmental anatomy of the seminal vesicles to gain a full understanding of the anatomy in adult patients. The seminal vesicles begin as bilateral dorsolateral bulbous dilations of the distal mesonephric ducts between 12 and 12½ weeks of gestation. By 13 weeks, these dilations have enlarged, and the ejaculatory ducts are beginning to form in the developing prostate (Brewster, 1985). The seminal vesicle and the ampulla of the vas deferens join posterior and superior to the prostate to form the ejaculatory duct (Nguyen et al, 1996). By the early portion of the seventh month, the seminal vesicle has multiple outpouchings and a widened main central lumen (Fig. 41-17) (Brewster, 1985).

The adult seminal vesicle measures 5 to 6 cm in length and 3 to 5 cm in diameter with a volume capacity of 13 cm, although seminal vesicles decrease in size as men age (Redman, 1987). At

Figure 41-17. Intrauterine (fetal) development of the seminal vesicles. A, Week 5. B, Week 8. C, Week 13. (Redrawn from Langman J. *Medical embryology*. 4th ed. Baltimore: Williams & Wilkins; 1981. p. 242–3.)

the terminal portion of the vas deferens within the prostate, the major lumen of the seminal vesicle empties into the ejaculatory duct. The ejaculatory duct is in continuity with the seminal vesicle but does not share the thick muscular wall of the seminal vesicle (Fig. 41-18) (Nguyen et al, 1996). The arterial supply to the

seminal vesicle is from the vesiculodeferential artery, branching off from the umbilical artery (Braithwaite, 1952). Venous drainage of the seminal vesicle follows the arterial supply draining through the vesiculodeferential veins and the inferior vesicle plexus. Innervation of the seminal vesicles is by the hypogastric nerve (adrenergic and cholinergic) and the pelvic nerve. Lymphatic drainage of the seminal vesicles is through the internal iliac nodes (Mawhinney and Tarry, 1991).

Congenital Anatomic Anomalies of the Seminal Vesicles

The incidence of unilateral seminal vesicle agenesis is 0.6% to 1%. Unilateral seminal vesicle agenesis may be associated with ipsilateral renal anomalies and unilateral absence of the vas deferens. This anomaly is thought to be secondary to an embryologic insult at week 7 of gestation before the separation of the ureteral bud from the mesonephric duct. If this insult occurs after week 7, it is unlikely that renal agenesis would be associated with the seminal vesicle agenesis (Hall and Oates, 1993). It is common to find bilateral absence of the seminal vesicles along with congenital

Figure 41-18. Posterior view of seminal vesicle anatomy in relation to the lower genitourinary tract (bivalved areas in dark gray).

bilateral absence of the vas deferens, which is typically associated with a cystic fibrosis transmembrane receptor mutation; 70% to 80% of affected men carry the genetic mutation associated with cystic fibrosis (Anguiano et al, 1994; Chillon et al, 1995). Treatment is necessary only when fertility becomes an issue.

Infectious Processes of the Seminal Vesicles

Infection of the seminal vesicles is seen in underdeveloped countries more frequently than in the United States. The causative agents are *Mycobacterium tuberculosis* and *Schistosoma haematobium*. The diagnosis of bacterial seminal vesiculitis can be made by transrectal or perineal needle aspiration. Surgery is not usually indicated, and culture-specific systemic antibiotics are the treatment of choice (Gutierrez et al, 1994). Very rarely, seminal vesiculectomy is necessary to prevent recurrent bacteremia or to eliminate persistent symptoms (Indudhara et al, 1991). Seminal vesicle abscesses are rare but have been associated with diabetes mellitus, long-term indwelling catheters, and endoscopic instrumentation (Gutierrez et al, 1994). Management of seminal vesicle abscesses is discussed subsequently with management of seminal vesicle cysts. Infection, obstruction, or the combination of the two can result in formation of calculi in the seminal vesicles. Patients with seminal vesicle calculi present with hematospermia, perineal pain, painful ejaculation, and infertility. These stones can be managed through an open or laparoscopic vesiculectomy, or the stone can be retrieved endoscopically using a small-caliber ureterscope (Ozgök et al, 2005; Cuda et al, 2006; Han et al, 2008).

Evaluation of Abnormalities of the Seminal Vesicles

Normal seminal vesicles are not palpable on digital rectal examination. When a seminal vesicle cyst is present, the area immediately above the prostate may be compressible on digital rectal examination. This same area may feel firm or solid when a seminal vesicle tumor is present. Semen analysis revealing a low seminal volume (<1.0 mL) and a lack of liquefaction and fructose may indicate ejaculatory duct obstruction or the absence of seminal vesicles (Goldstein and Schlossberg, 1988).

High-resolution transrectal ultrasonography (TRUS) has become the mainstay of imaging for the diagnostic evaluation of seminal vesicle pathology because it is a reliable and inexpensive imaging modality. On TRUS, the seminal vesicles can be found just superior to the prostate, between the bladder and the rectum, and can be well visualized in the anteroposterior and sagittal views. The normal seminal vesicles should appear as flat, elongated, paired structures in the above-described positions (Fig. 41-19). Along

Figure 41-19. Transrectal ultrasound examination of normal seminal vesicles. A, Transverse view. B, Sagittal view. B, bladder; ED, ejaculatory duct; SV, seminal vesicle; U, urethra.

with the seminal vesicles, the ampullae of the vas deferens, the ejaculatory ducts within the prostate, and the verumontanum can be imaged and evaluated by TRUS. Abnormalities such as seminal vesicle obstruction, aplasia, atrophy, and cyst formation can be identified by TRUS (Carter et al, 1989).

Seminal vesicle obstruction may result in seminal vesicle dilation that can be identified on TRUS with the following characteristics: anteroposterior diameter of greater than 15 mm, length greater than 35 mm, and large anechoic areas that contain sperm when aspirated (Jarow, 1996; Colpi et al, 1997). Asymptomatic cystic dilation of the seminal vesicle was incidentally found in 5% of men undergoing TRUS for prostate cancer screening (Wessels et al, 1992).

Hyperechoic solid masses in the seminal vesicles (isoechoic to the prostate) revealed on TRUS are concerning for tumor. If there is a unilateral solid mass in the seminal vesicle, it is more likely to be a primary tumor, whereas if it is present in bilateral seminal vesicles, it is more likely to be a secondary tumor from a primary prostate, rectal, or bladder malignancy. TRUS-guided biopsy or aspiration is necessary to assist in the diagnosis.

Computed tomography (CT) also has been used to evaluate the seminal vesicles. The normal appearance of the seminal vesicles on CT scan is that of paired structures just below the bladder with medium contrast similar to muscle (Goldstein and Schlossberg, 1988). A seminal vesicle cyst appears on CT scan as a well-defined retrovesicular fluid density with the attenuation of water, from 0 to 10 Hounsfield units, cephalad to the prostate gland (Fig. 41-20). CT accurately images seminal vesicle anomalies and is a good modality for imaging of the ipsilateral kidney concomitantly (Arora et al, 2007).

In cases of primary seminal vesicle malignancy, CT scan may be useful to characterize the lesion further before intervention. A tumor within the seminal vesicle on CT scan has a higher attenuation than the normal seminal vesicle, but the tumor may appear cystic secondary to tumor necrosis (King et al, 1989). It is impossible to differentiate malignant tumors from benign tumors on CT scan alone, although secondary tumors from the bladder, rectum, or prostate may have a more contiguous appearance (Sussman et al, 1986). The CT findings of a leiomyosarcoma of the seminal vesicle are described as an irregular mass, resulting in enlargement of the seminal vesicle with displacement of the prostate gland (Upreti et al, 2003). CT as well as MRI allows metastatic evaluation when seminal vesicle neoplasms are characterized further (Dahms et al, 1999).

MRI demonstrates more anatomic detail than CT and is an extremely useful imaging modality for the seminal vesicles. On

T2-weighted images, the ampulla of the vas deferens is visible approximately 71% of the time and exhibits low signal intensity. The seminal vesicles exhibit high signal intensity 79% of the time, low signal intensity 19% of the time, and a heterogeneous signal intensity 2% of the time on T2-weighted images (Roy et al, 1993). On T2-weighted images, the seminal vesicles generally have similar or higher intensity than fat in patients younger than 70 years old and typically have signal intensity lower than that of fat in patients older than 70. The convolutions of the seminal vesicles can be seen on T1-weighted imaging with contrast material (Fig. 41-21) (Secaf et al, 1991).

On MRI, seminal vesicle agenesis is best exemplified on T1-weighted axial images (Fig. 41-22). Care must be taken not to mistake the vesicoprostatic venous plexus for small glands. Arterio-venous malformations appear as large ectatic vessels adjacent to the lateral edge of the seminal vesicle. After androgen ablation, seminal vesicles demonstrate low signal intensity on T2-weighted images and appear small in size (Secaf et al, 1991). After pelvic radiation, seminal vesicles appear to be decreased in size in one third of patients. In patients after pelvic radiation, 63% of seminal vesicles had a normal MRI appearance, 21% had normal signal intensity but had fewer tubules, 8% had diffuse loss of signal intensity appearing hypointense to fat, and 8% were hypointense to fat on T2-weighted images (Chan and Kressel, 1991). A seminal vesicle cyst may have variable signal intensities on T1-weighted images but typically

Figure 41-20. Computed tomography scan of seminal vesicle (SV) cyst. B, bladder; U, ureters.

demonstrates fluid signal intensities on T2-weighted images and does not enhance with administration of intravenous gadolinium. Increased T1-weighted intensity represents increased proteinaceous concentration within the cyst or hemorrhage (Arora et al, 2007). Hemorrhagic seminal vesicle cysts have high signal intensity on T1-weighted and T2-weighted images (Sue et al, 1989). A benign primary mass of the seminal vesicle appears as a sharply margined mass arising from the seminal vesicle. The most common form of malignancy affecting the seminal vesicle is invasion of prostate cancer directly into the seminal vesicle. This invasion can make the seminal vesicle appear large but does not always do so, and the seminal vesicle has low signal intensity on T2-weighted images (Secaf et al, 1991). If there is a palpable seminal vesicle abnormality, TRUS should be performed, and biopsy should be performed if there is suspicion for malignancy. MRI of the prostate and seminal vesicles may provide significantly greater detail in determination of the difference between a primary seminal vesicle mass and local extension from a prostate, bladder, or rectal malignancy.

Surgical Approaches to the Seminal Vesicles

The surgical approach to the seminal vesicles depends mainly on the expertise and comfort of the surgeon, although the characteristics of the lesion may have an impact on the decision regarding the approach. The robotic-assisted laparoscopic approach is increasingly being used for the rare seminal vesicle lesion requiring excision.

Preoperative preparation for seminal vesicle surgery should include a bowel preparation the evening before surgery, in case of the uncommon occurrence of a bowel injury; GoLYTELY is recommended. A prophylactic systemic antibiotic is administered preoperatively, and two doses are given postoperatively. The use of intermittent compression stockings to prevent deep vein thrombosis during surgery is recommended.

Anterior Surgical Approaches to the Seminal Vesicles

The anterior surgical approach to the seminal vesicles has been well established and is a good open approach for patients with large benign masses or cysts and for patients with an ectopic ureter draining into a seminal vesicle cyst, so the kidney, ureter, and seminal vesicle all can be approached concomitantly. The transvesical approach has been well described (Walker and Bowles, 1968; Politano et al, 1975). A lower midline infraumbilical incision is made sharply, and the rectus muscles are divided in the midline. The space of Retzius is developed. The anterior bladder is exposed,

and a self-retaining retractor is placed. A longitudinal incision about 7 to 10 cm long is made in the anterior bladder wall, taking care to stay at least 3 to 4 cm proximal to the bladder neck. Moist sponges are placed in the bladder dome, and a bladder blade for the retractor is used to offer exposure gently. The ureteral orifices should be identified, and 8-Fr feeding tubes can be passed gently up the ureters to help with identification of the intramural ureters. A 5-cm longitudinal incision is made in the midline of the trigone with electrocautery on cutting current. When the incision goes through the posterior bladder muscle, the ampullae of the vas deferens should be visible just below the bladder neck. The seminal vesicles should be identified just lateral to the ampullae of the vas deferens on the prostatic base. The seminal vesicle is resected and removed. Care must be taken not to dissect too deep through Denonvilliers fascia posteriorly so as not to endanger the rectum. The posterior bladder wall is closed in two layers with 2-0 absorbable suture in the muscle and 4-0 absorbable suture in the mucosa. After closure of the bladder wall, a suction drain is placed in the perivesical space, not overlying the suture line, and is brought out through a separate stab incision (Fig. 41-23). This approach has a lower rectal injury rate, although it places the ureters at a higher risk for injury and is more prone to blood loss.

The perivesical approach is useful in pediatric patients with a large seminal vesicle cyst so that nephroureterectomy can be performed along with seminal vesiculectomy. A midline or Pfannenstiel incision offers adequate exposure for this approach. Finger dissection is used to dissect the bladder from the lateral pelvic sidewall on the side with the cyst. The seminal vesicle cyst should be readily identifiable, the seminal vesicle should be dissected free in its entirety, and a 1-0 chromic suture can be placed through the cyst as a traction suture to assist with dissection. The ureter must be identified crossing the vas deferens to prevent ureteral injury. The superior, and possibly the inferior, vesicle arteries may be sacrificed to offer exposure to the base of the seminal vesicle. The cyst should be dissected away from the bladder, and any seminal vesicle vessels can be clipped and divided. When the base of the seminal vesicle is accessed at the prostate–seminal vesicle junction, it can be ligated with 2-0 absorbable suture. Dissection of the proximal portion of the seminal vesicle must be done carefully by hugging the cyst so as not to injure the neurovascular bundle, which is directly lateral to the seminal vesicle. A clip is placed just distal to the previously placed suture, and the seminal vesicle is resected. A suction drain is placed adjacent to the seminal vesicle bed and is brought out through a separate stab incision. The drain and urethral catheter may be removed in 24 hours as long as there is not excessive drainage through the drain.

A third anterior approach to the seminal vesicles that can be performed in an open or laparoscopic manner is the retrovesical approach; this is useful for bilateral seminal vesiculectomies for bilateral small cysts or benign masses (de Assis, 1952). A urethral catheter is placed, a midline incision is made or standard pelvic ports are placed, and the peritoneum is entered. A transverse incision is made in the peritoneal reflection over the rectum at the posterior bladder wall, taking great care not to enter the rectum. The posterior bladder is sharply dissected off the anterior rectal wall until the ampullae of the vas deferens and the tips of the seminal vesicles are visible. The seminal vesicles are dissected free to the base at the prostate–seminal vesicle junctions and are ligated and resected. A suction drain is placed at the posterior bladder and brought out through a separate stab incision. The incision is closed (Fig. 41-24).

Posterior Surgical Approach to the Seminal Vesicles

Although the transcoccygeal approach is the least familiar to most urologists, it may be useful for patients who have had previous suprapubic or perineal surgeries. The patient is positioned in a prone, jackknife position (Kreager and Jordan, 1965). An L-shaped hockey-stick incision is made from midway on the sacrum, 10 cm from the tip of the coccyx, and angled at the tip of the coccyx down

Figure 41-23. Transvesical approach to seminal vesiculectomy. A, Vertical incision between the ureteral orifices. B, Transverse incision 2 cm superior to the bladder neck below the ureteral orifices. (Redrawn from Hinman F Jr. *Atlas of urologic surgery*. Philadelphia: Saunders; 1989.)

the gluteal cleft stopping 3 cm from the anus. The lateral side of the coccyx is carefully divided free from the rectum and removed. The layers of the gluteus maximus are swept aside until the rectosigmoid is reached, and then it is carefully dissected from the underside of the sacrum. The lateral rectal wall is divided free medially from the levator ani muscle until the prostate is encountered on the side of the seminal vesicle pathology. Dissection is carried superior to the base of the prostate in the midline until the ampulla of the vas deferens is identified with the seminal vesicle just lateral to the ampulla. The seminal vesicle should be dissected and resected as previously described. A Penrose drain should be placed at the bed of the seminal vesicle and brought out through a separate stab incision from the closure. The drain can be removed in 2 to 3 days if there is no drainage (Fig. 41-25).

Laparoscopic and Robotic-Assisted Surgical Approach to the Seminal Vesicles

Laparoscopic surgery on the seminal vesicles is most commonly performed concomitantly with prostate surgery. The technique for the laparoscopic approach to the seminal vesicles was first described in 1993 (Kavoussi et al, 1993). Laparoscopy also has been applied to seminal vesiculectomy without prostatectomy and has been reported in a case of amyloidosis of the seminal vesicle (Vandwalle et al, 2007). Robotic-assisted laparoscopy also has been used to excise seminal vesicle cysts (Moore et al, 2007; Selli et al, 2008). Patients are positioned in the supine position with careful padding of all pressure points, and the arms are tucked and padded. A split-leg table is necessary for the robotic-assisted technique. Wide cloth tape is applied across the chest and hips to secure the patient to the table, and the table is placed in steep Trendelenburg position. Before gaining access, a urethral catheter and an orogastric tube should be placed to decompress the bladder and stomach for subsequent trocar placement. To gain access, a Veress needle is placed periumbilically, and a pneumoperitoneum is achieved, not exceeding pressures of 15 mm Hg. After an adequate pneumoperitoneum is achieved, the laparoscopic ports can be placed, placing the first one with an optical trocar for the camera port and the following ones under direct laparoscopic visualization. The ports can be placed in either a horseshoe or a diamond arrangement for pure laparoscopy and can be placed in the same position as would be used for prostatectomy for robotic assistance (Fig. 41-26) (Menon et al, 2003; Lee et al, 2004). The peritoneum is incised between the two obliterated umbilical ligaments just anterior to the rectum in the pouch of Douglas. The seminal vesicles can be visualized and should be dissected carefully to avoid injury to the neurovascular bundles or the surrounding viscera. Monopolar energy should not be used to minimize injury to surrounding structures, and much of this dissection can safely be performed sharply. The seminal vesicle arterial pedicle can be managed with a clip or with bipolar cautery. The seminal vesicle should be dissected toward its junction with the ampulla of the vas deferens, and both can be clipped together at the base. The specimen can be placed in an extraction bag and can be removed through one of the laparoscopic ports. The ports are closed under visualization.

The extraperitoneal laparoscopic approach to the seminal vesicles was first described in 1997 and was performed concomitantly with radical prostatectomy (Raboy et al, 1997). In the following years, this approach gained more popularity (Bollens et al, 2001; Stolzenburg et al, 2003). A 1.5-cm periumbilical incision is made, and the preperitoneal space is entered. A balloon trocar is introduced into the preperitoneal space, and insufflation is performed under direct vision. The details of the technique are described further in Chapter 115.

Surgical Treatment of Seminal Vesicle Cysts

Seminal vesicle cysts are thought to be secondary to ejaculatory duct obstruction and can be congenital or acquired (Heaney et al, 1987; King et al, 1991; Conn et al, 1992). Seminal vesicle cysts are associated with ipsilateral renal agenesis or dysplasia in two thirds of patients; the cysts are secondary to maldevelopment of the distal mesonephric duct and are an error in ureteral budding (Beeby, 1974). Seminal vesicle cysts also have been associated with polycystic kidney disease. In one report, seminal vesicle cysts were identified in 60% of patients with polycystic kidney disease, and some authors recommend that all patients with seminal vesicle cysts undergo renal imaging (Alpern et al, 1991; Hihara et al, 1993; Danaci et al, 1998). Seminal vesicle cysts should be treated only if they are symptomatic or result in ejaculatory duct obstruction and affect fertility (Surya et al, 1988).

Seminal vesicle cysts can be drained by many techniques. TRUS-guided aspiration or transperineal aspiration can be performed on small seminal vesicle cysts that are symptomatic or obstructing the ejaculatory ducts. If the cyst reaccumulates fluid, resulting in recurrent symptoms or obstruction, it may be aspirated again

with the injection of a sclerosing agent such as tetracycline. A small abscess in the seminal vesicle can be managed similarly with drainage (Frye and Loughlin, 1988; Shabsigh et al, 1989; Gutierrez et al, 1994). If the seminal vesicle cyst is proximal, adjacent to the prostate, transurethral resection can be performed to unroof the cyst at the 5 o'clock and 7 o'clock positions just distal to the bladder neck (Frye and Loughlin, 1988; de Lichtenberg and Hvidt, 1989). The same outcome has been reported by incising the seminal vesicle cyst to drain it cystoscopically with the use of a Collings knife (Gonzalez and Dalton, 1998). Seminal vesicle abscesses can be managed in a similar fashion. Some groups reported using semirigid ureteroscopes to treat seminal vesicle cysts and abscesses (Razvi and Denstedt, 1995; Shimada and Yoshida, 1996; Okubo et al, 1998). If the

above-described techniques for drainage of seminal vesicle cysts are unsuccessful, open or laparoscopic excision can be performed (Moudouni et al, 2006). Seminal vesiculectomy along with nephroureterectomy should be performed in cases with an ectopic ureter. If these techniques for seminal vesicle abscess fail, open drainage is required (Kore et al, 1994).

Surgical Treatment of Tumors of the Seminal Vesicles

Benign tumors of the seminal vesicle that occur more commonly than malignant tumors include fibromas, leiomyomas, cystadenomas, schwannomas, and papillary adenomas (Mostofi and Price, 1973; Lundhus et al, 1984; Narayana, 1985; Mazur et al,

Figure 41-26. A, Positioning of the patient for laparoscopic seminal vesicle dissection. B, Diamond configuration of laparoscopic ports. C, Inverted U-shaped configuration of laparoscopic ports in obese patients. (From Winfield HN. Laparoscopic pelvic lymph node dissection for urological pelvic malignancies. *Atlas Urol Clin North Am* 1993;1:33–47.)

1987; Bullock, 1988; Gentile et al, 1994; Latchamsetty et al, 2002; Lee et al, 2006). Primary papillary adenomas and cystadenomas of the seminal vesicle typically occur in middle-aged men and are almost never bilateral, and they appear as simple cysts on imaging; the diagnosis is typically made on final pathology after excision (Mazur et al, 1987). Amyloid localized to the seminal vesicles also has been reported (Jun et al, 2003). Of men older than age 76 years, 20% have subepithelial deposits of amyloid in the seminal vesicles, and the reported incidence in male autopsies is 4% to 17% (Pitkanen et al, 1983; Ramchandani et al, 1993). Patients should be treated only if they are symptomatic and the diagnosis of amyloid of the seminal vesicle is made. Hydatid cysts of the seminal vesicle also have been reported (Kuyumcuoglu et al, 1991; Papathanasiou et al, 2006).

Seminal vesicle malignancies are extremely rare and are difficult to diagnose because patients are typically asymptomatic

until late in the course of the disease process. Primary malignancies of the seminal vesicles are extremely rare, and serum prostate-specific antigen and tissue biopsy can help differentiate primary malignancies from extension or metastasis of lymphoma, prostate, bladder, or rectal cancer. The low proliferative activity of the seminal vesicles is thought to account for the low incidence of primary malignancies of the seminal vesicle (Meyer et al, 1982). Primary adenocarcinoma of the seminal vesicle occurs in patients older than 50 years. Serum prostate-specific antigen is normal, and serum carcinoembryonic antigen is elevated (Mostofi and Price, 1973; Benson et al, 1984; Tanaka et al, 1987; Chinoy and Kulkarni, 1993; Thiel and Effert, 2002). Primary sarcoma of the seminal vesicle is an extremely rare malignancy, which is usually discovered late in the disease process and is diagnosed by biopsy (Benson et al, 1984; Chiou et al, 1985; Schned et al, 1986; Tanaka et al, 1987; Davis et al, 1988; Kawahara et al, 1988). All sarcoma

types of the seminal vesicle, including leiomyosarcoma, rhabdomyosarcoma, angiosarcoma, and müllerian adenosarcoma-like tumor, behave very aggressively, and radical extirpation has varying outcomes (Lamont et al, 1991; Laurila et al, 1992; Amirkhan et al, 1994; Berger et al, 2002). Cystosarcoma phylloides and seminoma also have been reported as primary malignancies of the seminal vesicles (Adachi et al, 1991; Fain et al, 1993). Primary squamous cell carcinoma of the seminal vesicle has been reported and treated with surgical extirpation followed by adjuvant radiation therapy with success with short-term follow-up (Tabata et al, 2002).

Solid seminal vesicle masses that are benign on biopsy and show no evidence of local spread should be treated with seminal vesiculectomy only if they are symptomatic, which is a very rare occurrence. Solid masses of the seminal vesicles that are proven to be malignant by biopsy or with a high suspicion for malignancy should be surgically treated, although the optimal treatment is still debated because there have been so few primary seminal vesicle malignancies treated at any institution. Large primary malignancies of the seminal vesicles have been treated with radical pelvic surgery: cystoprostatectomy with pelvic lymphadenectomy or pelvic exenteration. Adjuvant therapy has not proven to be effective, although the only survivors in the literature underwent radical surgery followed by pelvic radiation and/or androgen ablation.

Complications of Seminal Vesicle Surgery

Complications of seminal vesicle surgery are minimized by the surgeon selecting the approach that he or she is most comfortable and facile performing. The surgeon must be aware of the following complications that are specific to seminal vesiculectomy. Rectal or bladder injury may occur with any surgery on the seminal vesicle. If a preoperative bowel preparation was administered, and there is no gross fecal contamination, a two-layer closure of the rectum may be performed closing the mucosal layer with a running 3-0 absorbable suture and the submucosal layer with interrupted 4-0 silk sutures. The anus also should be dilated before the end of the case. A temporary colostomy should be considered with a large rectal injury or gross fecal contamination. The bladder should be closed in two layers, leaving a urethral catheter in place for 7 to 10 days postoperatively.

Complications of the laparoscopic approach include general laparoscopic complications, such as trocar injury to the bowel or great vessels, extraperitoneal insufflation, abdominal wall bleeding, and gas embolism. Bladder and rectal injuries may be repaired laparoscopically as long as there is not gross fecal contamination with rectal injuries. The distal ureter is close to the tip of the seminal vesicle, and if the ureter is injured, it may be repaired laparoscopically, although a ureteral replant may be necessary and performed open or laparoscopically, depending on the experience of the surgeon. It is recommended that a ureteral stent and a pelvic drain be left in such cases. The neurovascular bundle runs just lateral to the tips of the seminal vesicles; injury to the neurovascular bundle can result in erectile dysfunction, regardless of the surgical approach. Potential complications of endoscopic management of the seminal vesicles include postvoid dribbling secondary to urinary reflux and infection (Goluboff et al, 1995).

MANAGEMENT OF NONPALPABLE TESTICULAR LESIONS

Data in the literature regarding the management of incidentally found testicular lesions are limited. A testicular lesion is defined as incidental when it is asymptomatic and nonpalpable and in the presence of negative tumor markers (Carmignani et al, 2003). With the increased use and availability of ultrasonography, there has been an increase in detection of these lesions; however, the overall incidence of asymptomatic, incidental testicular lesions found with scrotal ultrasonography is low. In a large series of 3000 men who underwent scrotal ultrasonography for indications of scrotal pain,

KEY POINTS: SURGERY OF THE SEMINAL VESICLES

- Seminal vesicle secretions contribute 50% to 80% of the volume of the ejaculate.
- Unilateral seminal vesicle agenesis may be associated with ipsilateral renal anomalies and unilateral absence of the vas deferens.
- Normal seminal vesicles are not palpable on digital rectal examination.
- If there is a palpable seminal vesicle abnormality, TRUS and MRI should be performed, and biopsy should be performed if there is suspicion for malignancy.
- The surgical approach to the seminal vesicles depends mainly on the expertise and comfort of the surgeon, although the characteristics of the lesion may affect the decision regarding the approach.
- Benign and malignant tumors of the seminal vesicles are very rare.

flank pain, neck mass, and retroperitoneal mass, 15 (0.5%) were discovered to have incidental testicular lesions (Comiter et al, 1995). Another large series of 1300 scrotal ultrasound scans found 27 (2%) incidental testicular lesions (Carmignani et al, 2003).

Previous studies showed an increased incidence of testicular malignancies in infertile men (Jacobsen et al, 2000). Other risk factors for the presence of malignancy include palpable testicular lesions, history of cryptorchidism, testicular atrophy, and contralateral germ cell tumor. Histologically benign lesions are more common than malignant lesions for incidentally discovered nonpalpable testicular lesions (Sheynkin et al, 2004).

Some advocate for early surgical intervention for nonpalpable testicular masses (Müller et al, 2006) with 20% of these lesions being malignant. The testicle is delivered through an inguinal incision, and the lesion is localized using intraoperative ultrasonography (Horstman et al, 1994). Hopps and Goldstein expanded on this technique by using ultrasound-guided needle localization and microsurgical exploration to assist in tumor identification (Hopps and Goldstein, 2002).

Other authors support a more conservative approach. Eifler and colleagues (2008) reported that only 6% of incidentally found testicular lesions less than 1 cm were malignant based on tissue diagnosis. These authors stated that intratesticular, hypoechoic lesions less than 5 mm in patients with negative markers are likely benign and can be followed with serial imaging. Connolly and associates (2006) identified a highly select group of patients with incidental testicular lesions less than 1 cm to follow with serial ultrasound scans. In eight patients who met criteria, only one lesion (13%) progressed on serial imaging and was a seminoma. These authors concluded that although most patients with small lesions require surgical exploration, carefully selected patients who are highly compliant can be managed safely with serial imaging. The pathologic findings from these studies are summarized in Table 41-2.

Although these lesions are rare, they present a management dilemma for urologists. In this setting, the clinician must decide whether to pursue a more aggressive approach such as inguinal orchiectomy, inguinal exploration, and excision with frozen section or a more conservative, nonoperative approach with surveillance with serial ultrasound scans. A treatment algorithm for management of nonpalpable intratesticular lesions is shown in Fig. 41-27. Malignancy should be considered when any of the following are present: mass greater than 1 cm, severe oligospermia or azoospermia, atrophy, history of cryptorchidism, prior testicular malignancy, or elevated tumor markers. If the patient is at low risk for malignancy, it is reasonable to follow the patient with serial ultrasound scans. Patients must understand that changes in size or architecture of the lesion require surgical exploration.

Surgical, Radiologic, and Endoscopic Anatomy of the Kidney and Ureter

Mohamed Aly Elkoushy, MD, MSc, PhD, and Sero Andonian, MD, MSc, FRCS(C), FACS

Kidneys

Pelvicalyceal System

Anatomy of course does not change, but our understanding of anatomy and its clinical significance does change.

– Frank H. Netter, MD

Anatomy provides a roadmap for surgical procedures. This chapter presents the normal anatomy of the kidney and ureter. To make it more interesting for urologists, we provide clinical, radiologic, surgical, and endoscopic correlations. Of course, the human body never ceases to amaze explorers with its variations from the “normal.” With modern imaging technology, it has become possible to create three-dimensional (3D) virtual reality of each patient before surgical procedures. However, the surgeon is still advised to be cautious of the minute anomalies not appreciated on perioperative imaging studies.

KIDNEYS

Surface Anatomy and Relationships

The kidneys are paired ovoid, reddish-brown retroperitoneal organs situated in the posterior part of the abdomen on each side of the vertebral column. The kidneys lie on the psoas muscles; thus the **longitudinal axes** of the kidneys are oblique (arrows, Fig. 42-1 on the Expert Consult website), with the upper poles more medial and posterior than the inferior poles. Therefore, during percutaneous renal access, it should be noted that the lower pole of the kidney lies laterally and anteriorly relative to the upper pole. In addition, the medial aspect of each kidney is rotated anteriorly at an angle of approximately 30 degrees. The exact **position** of the kidney within the retroperitoneum varies during different phases of respiration, body position, and presence of anatomic anomalies. For example, the kidneys move inferiorly approximately 3 cm (one vertebral body) during inspiration and during changing body position from supine to the erect position. The position of the kidneys in the supine end-expiration is described here. Because of the inferior displacement of the right kidney by the liver, the right kidney sits 1 to 2 cm lower than the left kidney. Therefore the right kidney resides in the space between the top of the 1st lumbar vertebra to the bottom of the 3rd lumbar vertebra, whereas the left kidney occupies a space between the 12th thoracic vertebra and the 3rd lumbar vertebra.

Each kidney measures 10 to 12 cm in length, 5.0 to 7.5 cm in width, and 2.5 to 3.0 cm in thickness. Each adult male kidney

Ureters

weighs approximately 125 to 170 g; the kidney is 10 to 15 g smaller in females. The right kidney is slightly shorter and wider because of downward compression by the liver. The kidneys are relatively larger in children and have more prominent fetal lobulations, which generally disappear by the first year of life. In addition, the adult kidney's lateral contour might have a focal renal parenchymal bulge known as a **dromedary hump**, which is more common on the left side and has no pathologic significance. These dromedary humps are thought to be caused by the downward pressure from the liver or the spleen.

The **posterior relationships** of the kidneys are detailed in Figure 42-2 (on the Expert Consult website). Superiorly, the kidneys are related to the inferior edge of the diaphragm and the ribs. The right kidney is related to the 12th rib, and the left kidney is related to the 11th and 12th ribs. When the lower ribs are fractured during trauma, associated renal lacerations could occur. The upper poles of the kidneys come close to the diaphragm and underlying pleural cavity containing the lungs; thus any violations of the diaphragm during excision of large renal masses could lead to pleural tears and pneumothorax. Furthermore, **percutaneous access** to the upper pole of the kidneys above the 11th rib (10th intercostal space) is associated with increased risk for injuring pleura and even lungs. Therefore, when possible, subcostal (below the 12th rib) or 11th intercostal space (between the 11th and 12th ribs) access should be achieved (Fig. 42-3 on the Expert Consult website). More inferiorly, the kidneys are related to the psoas major muscle medially and both the quadratus lumborum and aponeurosis of the transversus abdominis muscles laterally. The subcostal nerve and vessels and the iliohypogastric and ilioinguinal nerves descend obliquely across the posterior surfaces of the kidneys (Fig. 42-4).

Because the kidneys are retroperitoneal organs, they are related **anteriorly** to other retroperitoneal and intraperitoneal organs (Fig. 42-5 on the Expert Consult website). The right kidney is related superiorly to the liver (both intraperitoneal and retroperitoneal bare portions) and superomedially to the adrenal gland. Inferiorly, the right kidney is related to the small intestine and hepatic flexure of the colon, and medially it is related to the second stage of the duodenum and head of the pancreas. The parietal peritoneum bridging the upper pole of the right kidney to the liver forms the **hepatorenal ligament**. Therefore excessive downward traction of the right kidney may cause capsular tear of the liver and may lead to excessive intraoperative bleeding. The left kidney is related to the stomach and spleen superiorly, adrenal gland superomedially, jejunum and splenic flexure of the colon inferiorly, and tail of the pancreas with splenic vessels medially. The parietal peritoneum bridging the upper pole of the left kidney to the spleen forms the

Figure 42-1. Normal rotational axes of the kidneys. **A**, Transverse view showing approximate 30-degree anterior rotation of the left kidney from the coronal plane, relative positions of the anterior and posterior rows of calyces, and location of the relatively avascular plane separating the anterior and posterior renal circulations. **B**, Coronal section demonstrating slight inward tilt of the upper poles of the kidneys. **C**, Sagittal view showing anterior displacement of the lower pole of the right kidney.

Figure 42-2. Posterior relationships of the kidneys. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

Figure 42-3. Subcostal and supracostal percutaneous access to an upper pole calyx. The supracostal approach provides more direct access and provides a better angle for endoscopy of the rest of the kidney. However, there is increased risk for pleural injury.

Figure 42-5. Anterior relationships of the kidneys and ureters. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

Figure 42-4. Posterior abdominal wall showing great vessels, kidneys, and adrenal glands. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

splenoarenal ligament. If excessive downward pressure is applied to the left kidney, splenic capsular tears may occur, leading to hemorrhage from the spleen.

The kidneys are surrounded by a smooth, tough fibrous capsule, which is easily removed under normal conditions. Each kidney and its vessels are surrounded by a **perinephric fat** that extends into its hollow vertical cleft, the **renal hilum**, which is the entrance to a space within the kidney called the **renal sinus**. The kidneys and adrenal glands, including the perirenal fat surrounding them, are enclosed by a condensed, membranous layer of **renal (Gerota) fascia**, which continues medially to fuse with the contralateral side (Fig. 42-6 on the Expert Consult website). This fascia extends inferomedially along the abdominal ureter as a **periureteral fascia**. The Gerota fascia encasing the kidneys, adrenal glands, and abdominal ureters is closed superiorly and laterally and serves as an anatomic barrier to the spread of malignancy and a means of containing perinephric fluid collections. Because it is open inferiorly, perinephric fluid collections can track inferiorly into the pelvis without violating the Gerota fascia.

The Gerota fascia is further surrounded by a layer of condensed fat called the **paranephric fat**, which is most obvious posteriorly and represents the extraperitoneal fat of the lumbar region. Superiorly, the Gerota fascia is continuous with the diaphragmatic fascia on the inferior surface of the diaphragm, and, inferiorly, the anterior and posterior layers of the Gerota fascia are loosely attached. The Gerota fascia is attached with the paranephric fat by collagen bundles. Therefore the kidneys are relatively kept

fixed in position by these collagen bundles, the Gerota fascia, and paranephric fat.

The relationships of the kidneys have important **surgical implications**. To access the kidneys, adrenals, or abdominal ureters, the Gerota fascia must be opened. To access the kidneys transperitoneally, the colon needs to be mobilized from the **white line of Toldt**, which is the lateral reflection of posterior parietal peritoneum over the ascending and descending colon. To access the right renal hilum, the second stage of the duodenum and head of pancreas need to be carefully mobilized using the Kocher maneuver. To access the left renal hilum, the tail of the pancreas together with the spleen and splenic vessels need to be mobilized medially.

Gross and Microscopic Anatomy

Two distinct regions can be identified on the cut surface of a bisected kidney: the cortex, which is a pale outer region, and the medulla, which is a darker inner region (Fig. 42-7 on the Expert Consult website). The renal medulla is divided into 8 to 18 striated, distinct, conically shaped areas that are frequently called renal pyramids. The apex of the pyramids forms the renal papilla, and each papilla is cupped by an individual minor calyx. The base of the pyramids is positioned at the corticomedullary boundary. The cortex and the medulla containing the renal pyramids could be differentiated on renal imaging studies (Fig. 42-8 on the Expert Consult website). Furthermore, these renal papillae could be inspected endoscopically (Fig. 42-9 on the Expert Consult website).

Figure 42-6. Schematic cross-sectional diagram demonstrating renal (Gerota) fascia. It shows the retroperitoneal position of the kidneys and their supportive tissues. (From Hutchinson M. *A brief atlas of the human body*. 2nd ed. Old Tappan [NJ]: Pearson Academic; 2006.)

Figure 42-7. Internal structure of the right kidney. (From Drake RL, Vogl W, Mitchell AWM. *Gray's anatomy for students*. Philadelphia: Churchill Livingstone; 2005.)

Figure 42-8. Cross-sectional imaging of the normal kidney. A, T1-weighted gadolinium-enhanced axial magnetic resonance imaging (MRI) of kidneys, including the inferior vena cava, aorta, left renal vein, and superior mesenteric artery. B, Coronal T2 MRI of the kidneys. C, Transverse ultrasound imaging of the kidney. D, Sagittal ultrasound imaging of the kidney. 1, kidney; 2, renal cortex; 3, renal medulla; 4, inferior vena cava; 5, left renal vein; 6, aorta; 7, renal collecting system.

Figure 42-9. Renal papilla in a calcium oxalate stone-former (A) where several Randall plaques (arrows) appeared as irregular white areas beneath the urothelium; the plaque site lacking a urothelial layer (arrowhead) may be the site where the stone was attached to papilla. Renal papilla in a non-stone former (B) where no distinct sites of Randall plaques were noted on papilla but a nodular-appearing structure (arrowhead) was noted alongside the papilla. (From Matlaga BR, Coe FL, Evan AP, et al. The role of Randall's plaques in the pathogenesis of calcium stones. *J Urol* 2007;177:31–8.)

The renal cortex is approximately 1 cm in thickness and covers the base of each renal pyramid peripherally and extends downward between the individual pyramids to form the **columns of Bertin** (see Fig. 42-7 on the Expert Consult website). Interlobar arteries traverse these columns of Bertin from the renal sinus to the peripheral cortex and decrease in diameter as they move peripherally. Therefore percutaneous access to the collecting system is usually performed through a renal pyramid into a calyx to avoid these columns of Bertin containing larger blood vessels. The pyramids and their associated cortex form the lobes of the kidney. The lobes are visible on the external surfaces of the kidneys in fetuses, and evidence of the lobes may persist for some time after birth.

The functional unit of the kidney is the nephron (Fig. 42-10). Approximately 0.4 to 1.2 million nephrons are found in each adult kidney. The nephron consists of a glomerulus, which is composed of a capillary tuft surrounded by epithelial cells and the thin, fibrous Bowman capsule. The glomerulus filters the blood at a rate of 125 mL/min, the glomerular filtration rate, which is considered an index of renal function. The filtrate passes into the Bowman space and then into the proximal convoluted tubule, through the thin and thick limbs of the loop of Henle, to the macula densa adjacent to the glomerulus, and into the distal convoluted tubule. It then enters the collecting tubules and the ducts of Bellini. After absorption of approximately 90% of this filtrate, the remaining part constitutes the urine, which drips from the collecting ducts into the calyces, then to the renal pelvis, ureter, and bladder. Three layers separate the filtered blood from the Bowman space: a single layer of endothelial cells, a thin glomerular basement membrane, and a layer of podocytes on the other side of that basement membrane. The proximal and distal convoluted tubules and the loop of Henle are lined by a single layer of cubical epithelial cells. The cells lining the collecting ducts are cubical to columnar and are more resistant to damage than those of the renal tubules. The calyces, pelvis, ureters, bladder, and urethra are lined by transitional epithelium, the urothelium, which may change and give rise to a transitional cell carcinoma of the urinary tract or urothelial carcinoma.

KEY POINTS: THE KIDNEY

- Because the kidneys lie on the psoas muscles, the longitudinal axes of the kidneys are oblique, with the upper poles more medial and posterior than the inferior poles.
- The Gerota fascia envelops the kidney and the adrenal gland on all aspects except inferiorly, where it remains open.
- From anterior to posterior, the renal hilar structures are the renal vein (V), renal artery (A), renal pelvis (U for ureter), and posterior segmental artery (A)—making the mnemonic VAUA.
- The kidney is divided into cortex and medulla. The medullary areas are pyramidal, more centrally located, and separated by segments of cortex, the columns of Bertin.
- Each renal pyramid terminates centrally in a papilla. Each papilla is cupped by a minor calyx. A group of minor calyces join to form a major calyx. The major calyces combine to form the renal pelvis

Radiologic Anatomy of the Renal Parenchyma

In a well-prepared plain kidney-ureter-bladder (KUB) radiograph, the renal shape, margins, dimensions, and location can be identified. Both kidney shadows are clearly visible and can be assessed with regard to their position and morphology. The psoas muscle line could also be appreciated; it disappears with retroperitoneal effusions. Radiopacities, calcifications, and radiolucencies could be identified (Fig. 42-11 on the Expert Consult website). In gray-scale ultrasonography, the renal cortices of newborn kidneys are isoechoic or hyperechoic to the liver and splenic parenchyma, because of the presence of loops of Henle and proportionately greater volume of glomeruli in the cortex than in adults (Hricak et al, 1983; Kasap

et al, 2006). In adults, the normal kidneys have smooth margins and are isoechoic to the liver. However, both renal cortices and pyramids are usually hypoechoic to the liver, spleen, and renal sinus. Compared with renal parenchyma, the renal sinus appears hyperechoic because of the presence of hilar adipose tissue, blood vessels, and lymphatics (Fig. 42-12 on the Expert Consult website). On unenhanced computed tomography (CT), the renal parenchyma is homogeneous, with a density ranging from 30 to 60 Hounsfield units (HU) that increases up to 80 to 120 HU after intravenous contrast injection. After 20 to 30 seconds of contrast injection, the arterial CT phase is reached, and the corticomedullary CT phase appears after 30 to 70 seconds, when contrast accumulates in the renal cortex. The nephrographic CT phase, after 80 to 120 seconds, equally enhances renal cortex and medulla and is considered to be the optimal phase for detection of renal neoplasms. Finally, the excretory CT phase, more than 3 minutes after contrast injection, shows the opacified pelvicalyceal system, ureter, and bladder (Fig. 42-13). Magnetic resonance imaging with T1 and T2 relaxation sequences provides information regarding lipid or fat content and enhancement characteristics of tissues. T1-weighted sequences show the renal cortex much brighter than renal medulla, whereas the cortex is slightly less intense than the medulla on T2-weighted sequences. The renal pelvis containing fat appears hyperintense on both T1- and T2-weighted sequences. After injection of contrast, the nephrographic and excretory phases start after 60 to 90 and 120 seconds of contrast injection, respectively (see Fig. 42-8 on the Expert Consult website).

Of all congenital anomalies encountered in newborns, 20% to 30% affect the kidneys and ureters (Schedl, 2007). Anomalies of number, rotation, ascend, and/or fusion may be encountered. Radiologically, renal malrotation is identified because the renal pelvis appears to arise centrally instead of its medial origin from the kidney. Some calyces are located medial to the renal pelvis, a hallmark of rotational anomalies. These renal calyces appear distorted with or without obstruction (Fig. 42-14 on the Expert Consult website). Arrest or exaggeration of normal ascent of the kidneys gives rise to renal ectopia and is usually associated with malrotation. Despite the ureteral length being appropriate for the kidney position, the impaired drainage results in urinary stasis and increased chances of infection and stone formation. Moreover, blood supply to the ectopic kidney is also aberrant, originating from adjacent vessels (see Fig. 42-14 on the Expert Consult website). A kidney may cross the midline and fuse with the opposite kidney (crossed-fused ectopia). The ureter from the ectopic lower kidney crosses the midline and usually inserts into the bladder in its normal position. The two kidneys may fuse by an isthmus at their lower pole, giving rise to the horseshoe kidney (Fig. 42-15 on the Expert Consult website). It is usually positioned low in the abdomen because of its arrest by the origin of the inferior mesenteric artery. The isthmus may contain a fibrotic band or functional renal parenchyma. This kidney is usually subjected to other anomalies, especially ureteropelvic junction obstruction (UPJO), vascular anomalies, duplication anomalies, stone formation, and urinary tract infections.

KEY POINTS: RADIOLOGIC ANATOMY OF RENAL PARENCHYMA

- Although normal kidneys are isoechoic to the liver, both renal cortices and pyramids are hypoechoic to the liver, spleen, and renal sinus.
- Echogenicity correlates to the severity of pathologic changes in renal parenchyma.
- The renal parenchyma is homogeneous on unenhanced CT.
- T1-weighted sequences show the renal cortex much brighter than the renal medulla, whereas the cortex is slightly less intense than the medulla on T2-weighted sequences.
- Blood supply to an ectopic kidney originates from adjacent vessels

Figure 42-11. Plain radiograph (kidney-ureter-bladder [KUB]). This 63-year-old woman presented with recurrent urinary tract infections and was found to have a smaller left kidney with staghorn calculus on KUB.

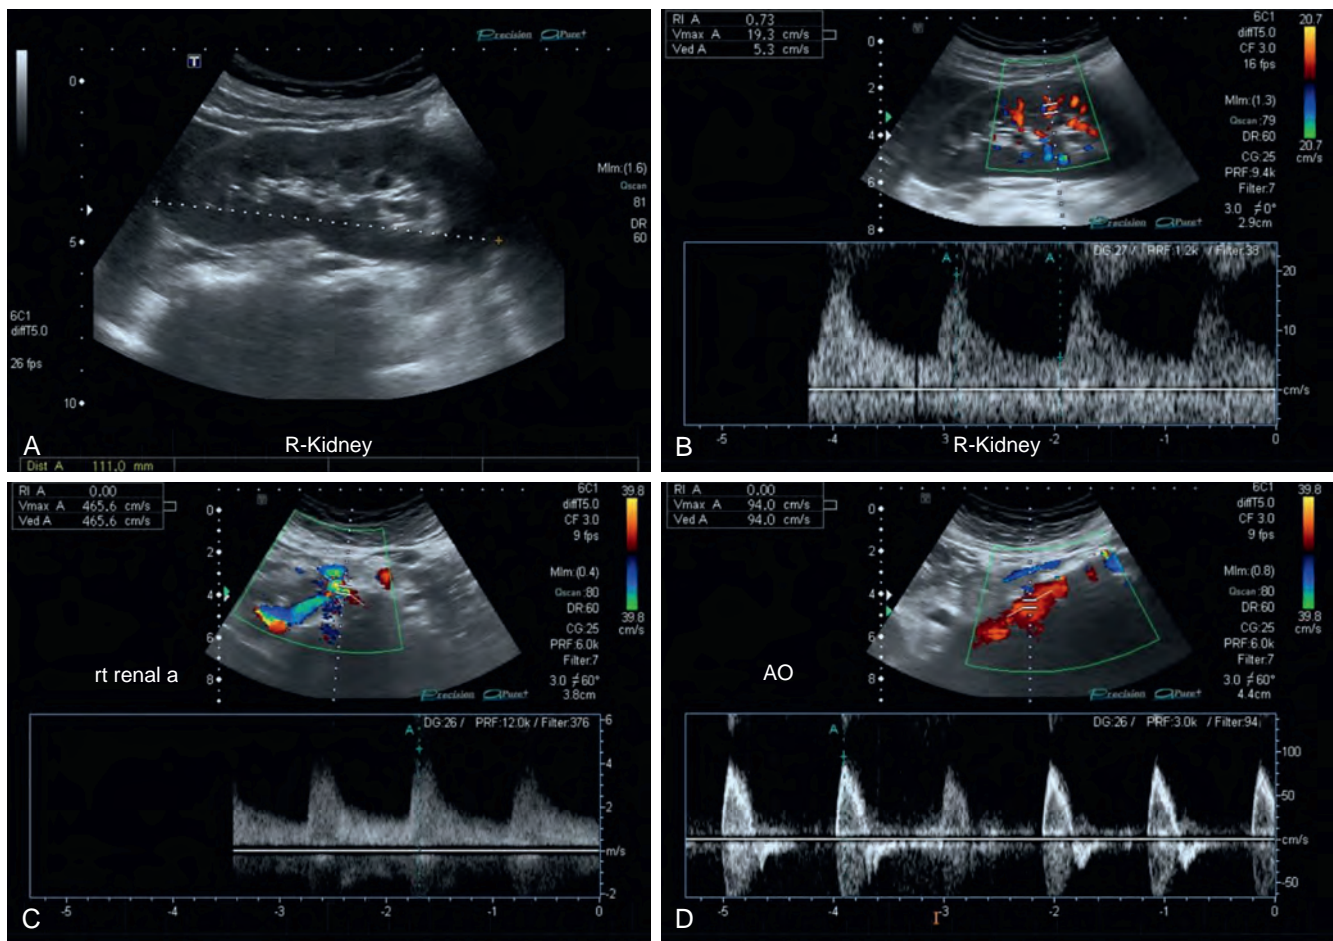

Figure 42-12. Renal ultrasonography and Doppler interrogation in a 65-year-old patient with poorly controlled hypertension. The resistive index within the renal parenchyma was 0.73. The right renal arterial peak systolic velocity reached up to 465.6 cm/sec at the ostium compared with peak systolic velocity of 94 cm/sec in the aorta (AO), suggesting severe (>50%) right renal arterial stenosis. A, Renal ultrasonography in B mode. B, Color Doppler of the renal parenchyma. C, Measurement of peak systolic velocity in right renal artery (rt renal a). D, Measurement of peak systolic velocity in the aorta. R, right.

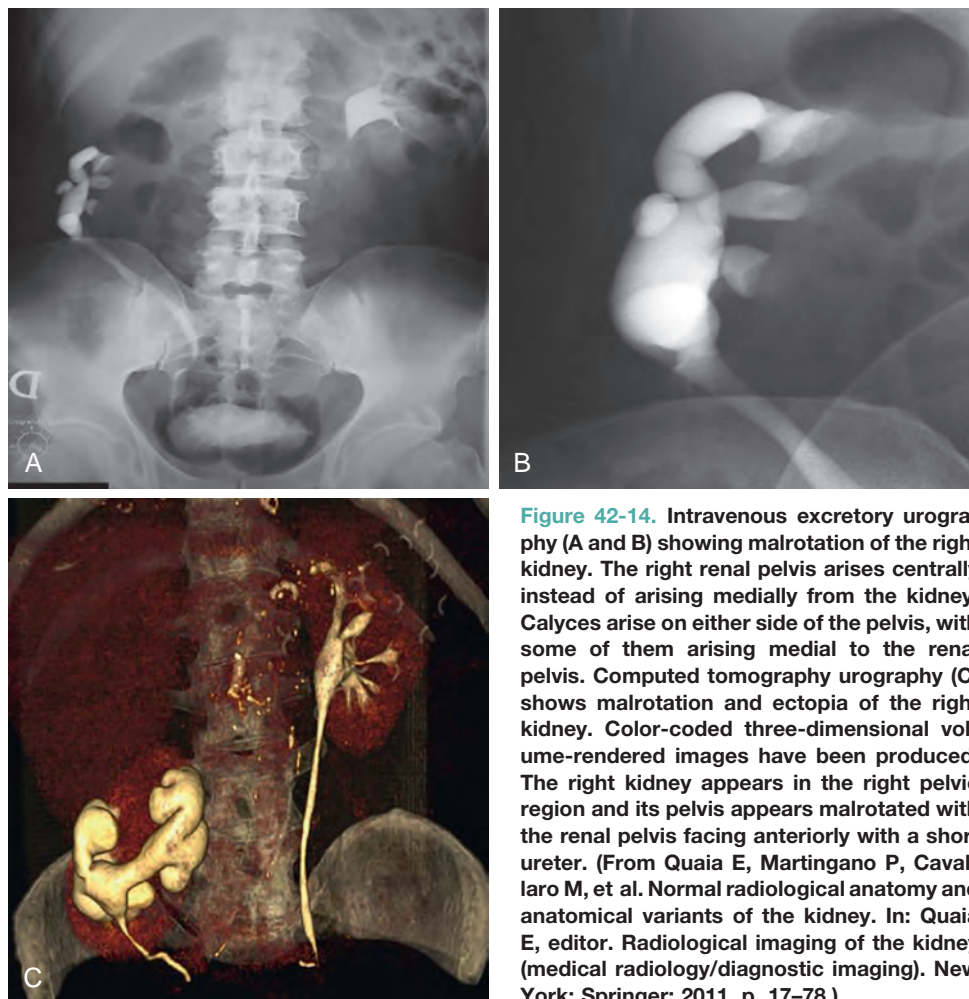

Figure 42-14. Intravenous excretory urography (A and B) showing malrotation of the right kidney. The right renal pelvis arises centrally instead of arising medially from the kidney. Calyces arise on either side of the pelvis, with some of them arising medial to the renal pelvis. Computed tomography urography (C) shows malrotation and ectopia of the right kidney. Color-coded three-dimensional volume-rendered images have been produced. The right kidney appears in the right pelvic region and its pelvis appears malrotated with the renal pelvis facing anteriorly with a short ureter. (From Quaia E, Martingano P, Cavallaro M, et al. Normal radiological anatomy and anatomical variants of the kidney. In: Quaia E, editor. Radiological imaging of the kidney (medical radiology/diagnostic imaging). New York: Springer; 2011. p. 17–78.)

(From Quaia E, Martingano P, Cavallaro M, et al. Normal radiological anatomy and anatomical variants of the kidney. In: Quaia E, editor. Radiological imaging of the kidney (medical radiology/diagnostic imaging). New York: Springer; 2011. p. 17–78.)

Renal Vasculature

The renal pedicle classically consists of a single artery and a single vein that enter the kidney via the renal hilum (Fig. 42-16). The renal arteries arise from the aorta at the level of the intervertebral disk between the L1 and L2 vertebrae where the longer right renal artery passes posterior to the inferior vena cava (IVC). Renal arteries give branches to the adrenal glands, renal pelves, and proximal ureters. After entering the hilum, each artery divides into five segmental end arteries that do not anastomose significantly with other segmental arteries. Therefore occlusion or injury to a segmental branch will cause segmental renal infarction. Nevertheless, the area supplied by each segmental artery could be independently

surgically resected. The renal artery usually divides to form anterior and posterior divisions. The anterior division supplies roughly the anterior two thirds of the kidney, and the posterior division supplies the posterior one third of the kidney. Typically, the anterior division divides into four anterior segmental branches: apical, upper, middle, and lower. The posterior segmental artery represents the first and most constant branch, which separates from the renal artery before it enters the renal hilum. A small apical segmental branch might originate from this posterior branch, but it arises most commonly from the anterior division. The posterior segmental artery from the posterior division passes posterior to the renal pelvis while the others pass anterior to the renal pelvis. **If the posterior segmental branch passes anterior to the ureter, UPJO may occur.** In 25% to 40% of kidneys, anatomic variations in the renal vasculature have been reported. **Supernumerary renal arteries** are the most common variation, with reports of up to five arteries, especially on the left side. The main renal artery may manifest early branching after originating from the abdominal aorta and before entering the renal hilum. These prehilum arterial branches should be detected in patients undergoing evaluation for donor nephrectomy. An accessory renal artery may arise from the aorta, between T11 and L4, and terminate in the kidney. Rarely, it may also originate from the iliac arteries or superior mesenteric artery. Accessory renal arteries are seen in 25% to 28% of patients and are considered the sole arterial supply to a specific portion of the renal parenchyma, commonly the lower and occasionally the upper pole of the kidney. These accessory renal arteries may contraindicate laparoscopic donor nephrectomy and result in severe bleeding if they are injured during endopyelotomy for UPJO. Multiple renal arteries that arise from the aorta or iliac arteries are frequently seen in horseshoe and pelvic kidneys. In approximately 5% of patients, the main and accessory right renal arteries pass anterior to the IVC.

There is a longitudinal avascular plane (line of Brodel) between the posterior and anterior segmental arteries just posterior to the lateral aspect of the kidney through which incision results in significantly less blood loss. However, this plane may have various locations that necessitate its delineation before incision either by preoperative angiography or intraoperative segmental arterial injection of methylene blue. This has important surgical implications. For example, during percutaneous access into the kidney, posterior calyces along the line of Brodel are preferred. Furthermore, during anastrophic nephrolithotomy (Boyce procedure), an incision is made through this avascular plane.

At the renal sinus, each segmental artery branches into lobar arteries, which further subdivide in the renal parenchyma to form interlobar arteries (Fig. 42-17 on the Expert Consult website). These interlobar arteries progress peripherally within the cortical columns of Bertin to give the arcuate arteries at the base of the renal pyramids at the corticomedullary junction. Note the close relationship of the interlobar arteries to the infundibuli of minor calyces. Interlobular arteries branch off the arcuate arteries and move radially, where they eventually divide to form the afferent arterioles to the glomeruli. Each afferent arteriole supplies a glomerulus, one of approximately 2 million glomeruli, where urinary filtrate leaves the arterial system and is collected in the glomerular (Bowman) capsule. Blood returns from the glomerulus via the efferent arteriole and continues as either secondary capillary networks around the urinary tubules in the cortex or descends into the renal medulla as the vasa recta.

The renal venous drainage correlates closely with the arterial supply, with the exception that unlike the arterial supply, venous drainage has extensive collateral communication through the venous collars around minor calyceal infundibula (Figs. 42-18 on the Expert Consult website and 42-19). Furthermore, the interlobular veins that drain the postglomerular capillaries also communicate freely with perinephric veins through the subcapsular venous plexus of stellate veins. The interlobular veins progress through the arcuate, interlobar, lobar, and segmental veins paralleling their corresponding arteries. Three to five segmental renal veins eventually unite to form the renal vein. Because the venous drainage communicates freely forming extensive collateral venous drainage of the

Blood supply of the kidney. **A and B,** Segmental branches of the right renal artery demonstrated by renal angiogram. **C,** Segmental circulation of the right kidney shown diagrammatically. Note that the posterior segmental artery is usually the first branch of the main renal artery and it extends behind the renal pelvis. *a*, artery.

kidney, occlusion of a segmental venous branch has little effect on venous outflow. The **right and left renal veins** lie anterior to the right and left renal arteries and drain into the IVC. Whereas the right renal vein is 2 to 4 cm long, the left renal vein is 6 to 10 cm. The longer left renal vein receives the left suprarenal (adrenal) vein and the left gonadal (testicular or ovarian) vein. The left renal vein also may receive a **lumbar vein**, which could be easily avulsed during surgical manipulation of the left renal vein. The left renal vein traverses the acute angle between the **superior mesenteric artery** anteriorly and the aorta posteriorly. In thin adolescents, the left renal vein may get compressed between the superior mesenteric artery and aorta, causing **nutcracker syndrome**. In approximately 15% of the patients, supernumerary renal veins are seen and often are retroaortic when present on the left. Accessory renal veins are more common on the right side, and the most common anomaly of the left renal venous system is the circumaortic renal vein, reported in 2% to 16% of patients. The retroaortic renal vein is less commonly seen than the circumaortic vein, in which the left renal vein

bifurcates into ventral and dorsal limbs, which encircle the abdominal aorta. In retroaortic renal vein, the single left renal vein courses posterior to the aorta and drains into the lower lumbar segment of the IVC.

In terms of imaging studies, Doppler ultrasonography clearly identifies renal arteries at their origin from the abdominal aorta (see Fig. 42-12 on the Expert Consult website). However, the main renal artery is often difficult to identify at baseline ultrasonography. Therefore computed tomography angiography (CTA) is currently considered the gold standard to assess renal arteries, with 100% sensitivity for identification of renal arteries and veins. The 3D volume-rendered CTA has emerged as a fast, reliable, and noninvasive modality that can reliably and accurately depict the number, size, course, and relationship of the renal vasculature. Arterial branches down to the segmental branches could be identified, but vessels smaller than 2 mm could be missed (see Fig. 42-15 on the Expert Consult website). Magnetic resonance arteriography uses no ionizing radiation, does not require arterial access, and includes

Figure 42-19. Venous drainage of the left kidney showing potentially extensive collateral circulation.

different imaging techniques to visualize renal vasculature. Contrast material can give faster, better resolution and more accurate images without artifacts.

KEY POINTS: RENAL VASCULATURE

- Each kidney is commonly supplied by a single renal artery, which arises directly from the abdominal aorta, and a single renal vein usually drains directly to the IVC.
- Each renal artery divides into five segmental branches: posterior, apical, upper, middle, and lower segmental arteries.
- The progression of arterial supply to the kidney is as follows: renal artery → segmental artery → interlobar artery → arcuate artery → interlobular artery → afferent arteriole → glomerulus → efferent arteriole.
- The veins anastomose freely throughout the kidney, whereas the arterial supply does not.
- Anatomic variations in the renal vasculature are common in 25% to 40% of kidneys.
- CTA is currently the gold standard to assess renal arteries. Accessory renal arteries are seen in 25% to 28% of patients and are considered the sole arterial supply to a specific portion of the renal parenchyma.
- Anomalies of renal veins are less common than those of the renal arteries.

Lymphatic Drainage of the Kidney

Interstitial fluid leaves the kidney by either a superficial capsular or a deeper hilar network (Fig. 42-20 on the Expert Consult website). Renal lymphatics are embedded in the periarterial loose connective tissue around the renal arteries and are distributed primarily along the interlobular and arcuate arteries in the cortex. The arcuate lymphatic vessels drain into hilar lymphatic vessels through interlobar lymphatics. As these lymphatics exit the renal hilum, they join branches from the renal capsule, perinephric tissues, renal pelvis, and upper ureter, where they empty into lymph nodes associated with the renal vein. Afterward, the lymphatic drainage varies considerably between the two kidneys. Left lymphatic drainage primarily goes into the left lateral para-aortic lymph nodes (between the

inferior mesenteric artery and diaphragm), with occasional additional drainage into the retrocrural nodes or directly into the thoracic duct above the diaphragm. Right renal lymphatic drainage primarily goes into the right interaortocaval and right paracaval lymph nodes (between common iliac vessels and diaphragm), with occasional additional drainage from the right kidney into the retrocrural nodes or the left lateral para-aortic lymph nodes.

Innervation of the Kidney

The kidney can function well without neurologic control, as evidenced by the successful function of transplanted kidneys (Fig. 42-21 on the Expert Consult website). Sympathetic preganglionic nerves originate from the 8th thoracic through 1st lumbar spinal segments, with contributions mainly from the celiac plexus and a lesser contribution from the greater splanchnic, intermesenteric, and superior hypogastric plexuses. Postganglionic sympathetic nerve fiber distribution generally follows the arterial vessels throughout the cortex and the outer medulla. These postganglionic fibers travel to the kidney via the autonomic plexus surrounding the renal artery. In addition, parasympathetic fibers from the vagus nerve travel with the sympathetic fibers to the autonomic plexus along the renal artery. The renal sympathetics cause vasoconstriction, and the parasympathetics cause vasodilatation.

PELVICALYCEAL SYSTEM

Understanding the collecting system anatomy is of utmost importance for appropriate radiologic interpretation and performance of different endourologic procedures. The upper pole of the kidney usually contains three calyces and less commonly two, whereas three or four calyces could be identified at the interpolar region and two or three calyces at the lower pole (Fig. 42-22). These calyces vary considerably not only in numbers but also in size and shape because of the different numbers of papillae they receive. A calyx may receive a single papilla, two, or even three. Compound papillae are often found in the polar regions of the kidney. The upper pole is usually drained by a single midline calyceal infundibulum, and the lower pole is drained by either a single midline calyceal infundibulum or by paired calyces. The hilar region is drained by anterior and posterior rows of paired calyces. The pelvicalyceal system may have the configuration of either a true pelvis or divided double calyceal pelvis. The true pelvis is the classic type in which the calyces drain directly through elongated necks into an elongated pelvis. This pelvis may be completely imbedded within the renal sinus (intrarenal pelvis) or mostly outside it (extrarenal pelvis). The renal pelvis is roughly pyramidal, with the base facing the parenchyma and the apex funneling down into the ureter. It usually has a capacity of 3 to 10 mL of urine.

In a divided (duplex) pelvis, it is divided at the hilum into upper and lower portions and drains a higher number of calyces than a normal pelvis. Its lower part is usually shorter but larger and often drains the hilar and the lower pole calyces. Therefore there is no direct connection between the upper and lower calyces. This usually becomes apparent during the excretory phase of a CT urogram or on retrograde pyelography. During percutaneous endoscopic evaluation of the kidney, the existence of a duplex pelvis should be considered if upper or lower pole calyces cannot be accessed through a particular calyceal access. Duplex systems are easier to recognize on retrograde nephroureteroscopy. When a duplex system is suspected during ureteroscopy, retrograde pyelography could be performed to illustrate the anomalous pelvicalyceal system.

Radiologic Anatomy of the Collecting System

After an iodinated contrast agent is injected for intravenous urography, nephrotomograms appear after 60 to 90 seconds that represent contrast material within the renal tubules. Fifteen minutes after contrast injection, a panoramic radiograph of the whole urinary tract can be obtained; the bladder finally appears 20 to 30 minutes

after contrast injection. Absence of contrast excretion 24 hours after intravenous contrast injection indicates a nonfunctioning kidney. **The pelvicalyceal anatomy is variable, and no simple rule defines calyceal organization.** Currently, CT urography has replaced intravenous urography, and multidetector CT provides the ability to obtain thin (<1 mm) collimated data of the entire urinary tract during a short single breath-hold (Van Der Molen et al, 2008). Magnetic resonance urography (MRU) has two consecutive phases: a static-fluid phase and an excretory phase. The static-fluid MRU is ideally indicated for evaluation of the obstructed or dilated collecting system. The practicability of excretory MRU depends on renal function, and its quality could be improved by a low-dose furosemide diuretic. Congenital variants of the pelvicalyceal system are common, representing approximately 4% of the population. The renal pelvis may be completely intrarenal, completely extrarenal, or a combination of both (Friedenberg and Dunbar, 1990). The infundibula insert directly into the extrarenal pelvis, giving the impression of a dilated pelvis. Receiving the tip of renal papilla, the renal calyx is a concave structure with two side projections, the fornices, which surround the papilla of the renal medulla. Multiple single calyces fail to divide completely, forming a larger compound calyx that normally can be observed in the upper and lower poles of the kidneys. Each kidney contains an average of 7 to 9 calyces, although this number may vary considerably from 4 to 19 or even more. Megacalycosis represents a nonobstructive asymptomatic congenital dilatation of some or all renal calyces while the renal pelvis and ureter are normal. It involves all calyces uniformly and usually is

associated with a greater number of calyces than normal. Calyceal diverticula represent a focal extrinsic dilatation of a renal calyx that is connected to the calyceal fornix and projects into the renal cortex, not into the medulla. The renoureteral unit may show duplication anomalies, including a bifid renal pelvis and complete or incomplete ureteral duplication. Two separate pyelocalyceal collecting systems may be present in one kidney, ranging from a bifid pelvis to a bifid ureter (ureteropelvic duplication).

URETERS

The ureters are bilateral muscular retroperitoneal ducts with narrow lumens that carry urine from the kidneys to the urinary bladder (see Fig. 42-22). Each ureter runs inferiorly as a narrow continuation of its renal pelvis at the UPJ, passing over the pelvic brim at the bifurcation of the common iliac artery. They then run along the lateral wall of the pelvis to enter the urinary bladder. In adults, the ureter is 22 to 30 cm in length with a diameter of 1.5 to 6 mm; in neonates it measures 6.5 to 7.0 cm long. In the retroperitoneum, the ureter is situated just lateral to the tips of the transverse processes of the lumbar vertebrae. The ureters occupy a sagittal plane that intersects the tips of the transverse processes of these lumbar vertebrae. The ureter is arbitrarily divided into proximal (upper), middle (over the sacrum), and distal (lower) segments. However, according to international anatomic terminology the ureter consists of abdominal (from renal pelvis to iliac

vessels), pelvic (from iliac vessels to the bladder), and intramural segments.

The abdominal parts of the ureters are adherent to the retroperitoneum throughout their entire course and extend from the renal pelvis to the pelvic brim. From the back, the surface anatomy of the ureter corresponds to a line joining a point 5 cm lateral to the L1 spinous process and the posterior superior iliac spine. Normally, three constrictions could be identified radiologically in each ureter; at its junction with the renal pelvis (UPJ), where it crosses the iliac vessels, and during its passage through the wall of the urinary bladder (intramural ureter) or ureterovesical junction (see Fig. 42-22). These constricted areas are potential sites of obstruction by ureteral calculi.

Posteriorly, both ureters descend anterior to the psoas major muscle and then cross the ventral surface of transverse processes of the 3rd to 5th lumbar vertebrae and enter the pelvis at the bifurcation of the common iliac vessels (see Figs. 42-4 and 42-5 on the Expert Consult website). The bifurcation of the common iliac vessels is used intraoperatively as a landmark to look for the ureter. The genitofemoral nerve runs on top of the psoas major muscle behind the ureter. The right ureter begins behind the descending part of the duodenum, where it is crossed by the gonadal vessels (testicular or ovarian), which is called “water under the bridge.” The left ureter is covered at its origin by the initial part of the jejunum. The gonadal vessels cross the left ureter after running parallel to it for a small distance. The inferior mesenteric artery and its terminal branch, the superior rectal artery, follow a curved course close to the left ureter. Therefore, as the left ureter approaches the pelvis, it is crossed by the left colic vessels, the sigmoid colon, and its mesocolon. Just above the entry to the pelvis, the ureter is still covered by peritoneum by virtue of the ureteral fold. This location at the pelvic brim represents one of the most common areas of ureteral injury. Furthermore, the close relationship of the ureter with the terminal ileum, appendix, right and left colons, and sigmoid colon makes it susceptible for encroachment of inflammatory and malignant processes, resulting in clinical presentations ranging from microhematuria to ureteral obstruction or even fistulae.

The pelvic segment of the ureter is approximately 15 cm long—a half of its total length. At the pelvic inlet, it crosses the common iliac vessels near their bifurcation. This crossover point is usually at the bifurcation of the common iliac artery into the internal and external iliac arteries, making this a useful landmark for pelvic procedures. The ureter then runs downward and laterally toward the ischial spine on the lateral pelvic wall along the anterior border of the greater sciatic notch, dorsally accompanied by the internal iliac artery and its visceral branches and the venous plexuses as well. It is still closely related to the posterior parietal peritoneum. At the ischial spine, the ureter turns medially to descend in the endopelvic fascia with branches of the hypogastric nerves. At the lateral wall of the pelvis, this part of the ureter crosses the obturator artery, vein, and nerve. In males, the vas deferens loops medially over this part while the ureter passes the ampulla of the vas deferens and the seminal vesicles just before it enters the bladder. In females, the descending part of the pelvic segment of the ureter courses posterior to the ovary to form the posterior boundary of the ovarian fossa. The ureter then passes through the base of the broad ligament and swings in a convex curve to cross under the uterine vessels “water under the bridge” in a sagittal direction approximately 1.5 to 2 cm adjacent to the supravaginal part of the uterine cervix. The terminal ureter runs forward, accompanied by the neurovascular bundle of the bladder and passes the anterior vaginal fornix just before entering the bladder. This close proximity of the ureter to the uterine vessels is the cause of ureteral injuries during gynecologic procedures. In the case of vaginal surgery, there is a high risk for injury especially for the left ureter that crosses the anterior vaginal fornix closer than the right ureter.

Near the bladder, the terminal ureter is enveloped by a muscular layer, the Waldeyer sheath, and then pierces the bladder wall obliquely as the intramural segment (Fig. 42-23 on the Expert Consult website). The length of this intramural part of the ureter in adults is 1.2 to 2.5 cm, and in neonates it is approximately 0.5 to

0.8 cm long. The Waldeyer muscle bundles of the ureter coalesce with those of the detrusor muscle of the bladder wall. Therefore reflux of urine from the bladder to the ureter is prevented during increased intravesical pressure, such as during micturition. Another important feature of the 3D course of the ureter that is critical to appreciate and follow during rigid ureteroscopy is the angulation of the ureter as it courses through the retroperitoneum. When approaching from the retrograde direction, it is important to note that the ureter courses anterolaterally as it goes along the lateral pelvic wall. Then, as it crosses the pelvic brim, it angulates posteriorly to continue as the proximal ureter. Following the 3D course of the ureter along a safety guidewire reduces the risk for perforation, especially in patients with large impacted stones.

Radiologic Anatomy of the Ureter

The ureter could be delineated by excretory urography during expiration, because it may be kinked during inspiration as a result of downward movement of the kidney (Friedenberg and Dunbar, 1990). For radiologic purposes, radiologists describe three segments of the ureter: a proximal portion extending from its origin down to the upper border of the sacroiliac joint, a middle portion lying over the sacroiliac joint, and the remaining segment from the lower border of that joint to its entrance into the bladder, which represents the distal portion of the ureter.

The course of the ureter and its bilateral symmetry are subject to great variability. It may descend laterally away from the margin of the transverse processes or be displaced medial to the renal pedicle. A medially displaced right ureter might normally be seen in young black males (Adam et al, 1985). The right ureter may run medially behind the vein at the level of 3rd lumbar vertebra before it returns back to its lateral position. **It should be noted that the entire length of the ureter is rarely seen in a single film of the excretory urography because of its peristaltic activity.** Otherwise, ureteral atony or obstruction should be suspected (Mellins, 1986). Similarly, crossing vessels may compress the ureter and simulate areas of stricture. **Therefore the diagnosis of a ureteral stricture should not be based on a single film of excretory urography with the presence of ureteral dilatation proximal to the site of narrowing.** Ureteral duplication may be complete or incomplete (partial). Complete duplication results from the development of a second ureteric bud, and the two ureters are inserted into the bladder separately. The partial type results from redundant duplication of the single ureteric bud in which the two ureters join together above the bladder to form a single stump draining into the bladder. Complete ureteral duplication with a common or ectopic entry of the upper pole moiety, is less common than incomplete duplication. The ureter draining the upper segment of the kidney prevalently inserts in the bladder inferior and medial to the ureter draining the lower segment of the kidney (Weigert-Meyer rule). These ectopic orifices are prone to ureterocele and/or vesicoureteral reflux. The lower moiety of the completely duplicated system is generally normal. Ureteral duplication also may be bilateral. Triple moiety may be observed. In diagnosis of renal or ureteral displacement, CT scans have replaced lateral views of conventional radiography. In a standard lateral view, the normal renal collecting system should not project anterior to the spine and the ureter stays behind the anterior margin of the vertebral bodies till the level of L4. After this, the ureter lies anterior to the vertebral body by approximately one-fourth the width of the vertebral body (Friedland et al, 1983). In elderly patients with atherosclerotic vessels, ureteral narrowing at the pelvic brim at its crossing to the common iliac vessels may produce a posterior indentation that may appear as an extrinsic filling defect. Dilatation proximal to that point may be differentiated from obstruction by the absence of pelvicalyceal dilatation without delay in emptying on prone or erect films (Friedenberg and Dunbar 1990). Medial displacement of both pelvic ureteral segments might result from retroperitoneal fibrosis or pelvic lipomatosis, or it may appear after abdominoperineal surgery. However, medial displacement and concavity of a single pelvic ureter may result from enlarged hypogastric nodes, a bladder diverticulum, or

Figure 42-23. Intramural portion of the distal ureter. (From Frober R. Surgery illustrated: surgical atlas, surgical anatomy of the ureter. BJU Int 2007;100:949–65.)

aneurysmal dilatation of the hypogastric artery. Nevertheless, this may be a normal finding in adult women if only the right ureter is affected because of the uterine tilt to the left. In older men, benign prostatic hyperplasia may result in elevation of the bladder floor enough to cause the intramural segment of the ureter to curve superiorly, giving a characteristic “fish hook” or “hockey stick” appearance on excretory urography (Olsson, 1986).

KEY POINTS: RADIOLOGIC ANATOMY OF THE URETER

- It is important to have the patient empty the bladder to evaluate the distal ureter appropriately.
- Radiologically, the ureter is divided into three segments: a proximal portion from UPJ to the sacroiliac joint, a middle portion lying over the sacroiliac joint, and a distal portion from the lower border of that joint to its entrance into the bladder.
- The entire length of the ureter is rarely seen on a single film of the excretory urography because of its peristaltic activity.

Arteries, Veins, and Lymphatic Drainage of the Ureters

The abdominal portion of the ureter is supplied mainly by arterial branches medially from the main renal arteries (Fig. 42-24 on the Expert Consult website). However, this segment may be uncommonly supplied by branches arising from the abdominal aorta or gonadal arteries. These branches approach the ureters medially and divide into ascending and descending branches, forming a longitudinal anastomosis on the ureteral wall. However, despite this anastomotic plexus, ureteral ischemia is not uncommon if these small and delicate ureteral branches are disrupted. Surgeons are trained to handle ureters gently to avoid unnecessary lateral retraction and removing periureteral adventitial tissues containing the blood supply to minimize ureteral ischemia and subsequent stricture. The mid-ureter is supplied by branches arising posteriorly from the common iliac arteries. The blood supply to the distal ureter comes laterally from the superior vesical artery, a branch of the internal iliac artery. Therefore the blood supply of the ureter is medially in the proximal part, posteriorly in the mid-portion, and laterally in the distal portion. Therefore endoureterotomy should be performed laterally in the proximal ureter, anteriorly in the mid-portion, and medially in the distal ureter. Another important surgical caveat is to control the obliterated umbilical artery before mobilizing the most distal aspect of the ureter as it enters the bladder.

Veins draining the abdominal part of the ureters drain into the renal and gonadal veins. **Venous drainage of the mid- and distal ureters is into the common and internal iliac veins.** The lymphatics of the ureter form plexuses within its muscular and adventitial layers. The lymphatics from the left abdominal ureter drain into the left para-aortic lymph nodes, and the lymphatics from the right abdominal ureter drain into the right paracaval and interaortocaval lymph nodes. Lymphatic vessels from the middle part usually drain into the common iliac lymph nodes, whereas lymphatics from its intrapelvic part drain into the common, external, and internal iliac lymph nodes.

KEY POINTS: URETERS

- The course of the ureter begins posterior to the renal artery and continues along the anterior edge of the psoas muscle.
- The gonadal vessels cross anterior to the ureter in this region (*water under bridge*). The ureter next passes over the bifurcation of the common iliacs into the internal and external iliacs.
- The blood supply of the proximal ureter is medially, mid-ureter is posteriorly, and distal ureter is laterally.

Nerve Supply of the Ureter

The ureter receives a rich autonomic nerve supply that originates from the celiac, aortorenal, and mesenteric ganglia, together with the superior and inferior hypogastric (pelvic) plexuses. The sympathetic supply to the ureter arises from the preganglionic fibers of the 11th and 12th thoracic and 1st lumbar segments. Parasympathetic vagal fibers supply the upper part of the ureter via the celiac plexus, and the lower portion is supplied by the sacral segments S2 to S4. Therefore afferent nerves from the upper portion of the ureter reach the spinal cord with the sympathetic fibers between T11 and L1 and those from the lower ureter travel via the pelvic plexus between S2 and S4. These fibers conduct afferent sensory stimuli from the ureters and have a minor, if any, role in the control of ureteral motility. This is because excised portions of the ureter continue to contract without nervous control and denervation of the lower portion of the ureter does not result in reflux. As mentioned earlier, the peristalsis of the ureter originates from pacemakers in the minor calyces. Thus the exact role of autonomic input of the ureters is unclear. Distention of the renal capsule and the collecting system causes stimulation of renal pain fibers that carry signals through the sympathetic nerves, thus resulting in visceral-type referred pain in the flank, groin, or scrotal (labial) regions.

Microscopic Anatomy of the Ureter

The ureter consists of three distinct layers: the innermost is the mucosa, the middle muscular layer is the muscularis, and the outer layer is the adventitia. The mucosa consists of transitional epithelium, which has four to six layers of cells when the ureter is contracted. These cells encircle a large number of junctional complexes containing consistent level of keratin precursors that is responsible for the waterproof property of this layer. The mucosa also contains many longitudinal folds that give the empty ureter a characteristic stellar outline. The epithelium rests on a layer of connective tissue, the lamina propria, which contains the blood vessels and nerve fibers to the ureter (Fig. 42-25 on the Expert Consult website).

The muscular wall of the ureter consists of two longitudinal layers separated by a middle circular layer that may not be distinct from each other, especially in the abdominal segment of the ureter. Mostly, these muscle fibers appear to be spirally arranged by the light microscopy. However, in the distal ureter, the inner spirals are steep and the outer spirals are horizontal, thus appearing as inner longitudinal and outer circular layers in cross section. These smooth muscle layers are contiguous with the smooth muscle covering the minor renal calyces, where the pacemaker is located to initiate the rhythmic peristalsis to deliver urine.

The outermost layer, the adventitia, consists of a dense network of collagen and elastic fibers, including many blood vessels and unmyelinated nerve fibers among them. This layer is continuous proximally with the capsule at the renal pelvis while it is thickened distally by a specialized muscle fibers and fibrous tissue to form the Waldeyer sheath.

In a normal kidney, the UPJ does not differ histologically from the renal pelvis. However, in an obstructed kidney, the longitudinal muscle fibers are significantly increased with more collagen deposits around the muscle fibers in addition to attenuation of muscle bundles, leading to the physiologic obstruction known clinically as UPJO.

Endoscopic Anatomy of the Ureter and Pelvicalyceal System

Once the cystoscope is inside the bladder neck, the trigone can be seen as a raised, smooth triangle. The apex of that triangle is situated at the bladder neck, and its base is formed by the interureteral ridge or Mercier's bar, extending between the two ureteric orifices. The interureteral ridge is more prominent in males than females, and

Figure 42-24. Arterial supply of the left ureter.

Figure 42-25. Transverse section through the ureter. Inner longitudinal layer is distinguished from outer circular and oblique muscle fibers. The rich vascular supply of the ureter is also demonstrated. LP, lamina propria; TC, transitional epithelium. (Courtesy Dr. Hossein Saboorian.)

the ureteric orifices are symmetrically located along it, approximately 1 to 2 cm from the midline. The trigone is the most vascular part of the bladder and is formed by an extension of the longitudinal muscle fibers of the ureters over the detrusor muscle. Therefore it appears cystoscopically to be more deeply colored than the rest of the bladder.

The normal ureteric orifice may appear as a volcano or a horse-shoe that is prominent and obvious on endoscopy. However, it might look like a slit that can be identified with only meticulous examination. It is pushed out laterally during bladder filling and may be quite variable in position and appearance. In normal bladder, ureteric orifices are usually surrounded by prominent mucosal vessels (Bagley et al, 1985).

The ureteric orifices are classified according to their position or configuration. They are normally located at the medial aspect of the trigone (position A). However, they may be located at the lateral wall of the bladder or at its junction with the trigone (position C) or in between positions A and C (position B) (Lyon et al, 1969). In terms of configuration, grade 0 indicates a normal ureteric orifice that looks like a cone or a volcano. Grades 1, 2, and 3 describe stadium, horseshoe, and golf-hole orifices, respectively. **The higher the grade of the orifice, the higher tendency to be laterally located and to reflux** (Fig. 42-26 on the Expert Consult website).

The intramural ureter represents the narrowest part of the ureter, with an average diameter of 3 to 4 mm. It extends from the ureteric orifice for approximately 1.5 cm, posterolaterally for 0.5 cm, and then obliquely through the detrusor hiatus for approximately 1 cm (Politano, 1972). Being the narrowest ureteral segment, the intramural ureter may need to be dilated before ureteroscopy. The other ureteral narrowing areas at the pelvic brim and UPJ are identified endoscopically by being stenotic and relatively nondistensible. However, they are relatively wider than the intramural segment. They can be easily instrumented with enough pressure from the irrigation fluid. The pulsating iliac vessels could be seen endoscopically as the ureters cross the pelvic brim and angulate posteriorly in the proximal portion.

The proximal ureter goes straight up to the UPJ; the ureter lies on the psoas major muscle, with the appearance of a typical stellate nondistended ureter. The UPJ could be identified easily endoscopically during its frequent opening and closing. The UPJ merges into the wider and more dependent part of the renal pelvis. Of interest, the respiratory movement of the kidney could be seen by endoscopy after passing the relatively fixed UPJ. The kidneys lie on the diaphragm, and thus they are affected by the respiratory movements. **Therefore, during ureteroscopy, the tidal volume could be decreased to minimize renal excursions during respiration.** Moreover, the physiologic ureteral contractions or peristalsis can be observed endoscopically. It is important to wait for the ureter to relax before pushing the ureteroscope to avoid mucosal trauma (Andonian et al, 2008b, 2010b).

The UPJ represents the apex of the funnel-shaped or conical normal renal pelvis. An extrarenal pelvis is usually larger and has longer major calyceal infundibula than an intrarenal pelvis. In the renal pelvis, the flexible ureteroscope first faces the ostia of the major calyces, which look like circular openings separated by carinae. Then the flexible ureteroscope enters a long tubular infundibulum that branches into the minor calyces. These infundibula usually connect the ostia of major calyces with their apex. For a flexible ureteroscope to pass from the axis of the upper ureteral

segment to the axis of the lower infundibulum, it should be deflected 140 (104 to 175) degrees at the ureteroinfundibular angle (Bagley and Rittenberg, 1987).

A circular muscle layer extends around the base of the papilla to help expel urine jets from papillary ducts. The renal papillae appear endoscopically as protruding discs surrounded by calyceal fornices, paler in color than the pink friable epithelium covering the papillae. Each papilla represents the apex of a renal pyramid, receiving the papillary ducts of Bellini that drain the pyramids. These ducts are minute openings that become more dilated and obvious with distal obstruction (Andonian et al, 2008a, 2010a).

KEY POINTS: ENDOSCOPIC ANATOMY

- The trigone is the most vascular part of the bladder and is formed by an extension of the longitudinal muscle fibers of the ureters over the detrusor muscle.
- Both ureteric orifices are rarely seen in a single endoscopic view.
- The interureteral ridge is more prominent in males than females, and the ureteric orifices are symmetrically located along it, approximately 1 to 2 cm from the midline.
- The intramural ureter represents the narrowest part of the ureter, with an average diameter of 3 to 4 mm.
- The extrarenal pelvis is usually larger and has longer major calyceal infundibula than the intrarenal pelvis.
- The renal papillae appear endoscopically as protruding discs surrounded by calyceal fornices, paler in color than the pink friable epithelium covering the papillae.

Effect of Pregnancy on Ureteral Function

Effect of Drugs on the Ureter

The function of the ureter is to transport urine from the kidney to the bladder. Under normal conditions, ureteral peristalsis originates with electrical activity at pacemaker sites located in the proximal portion of the urinary collecting system (Bozler, 1942; Weiss et al, 1967; Constantinou, 1974; Gosling and Dixon, 1974; Tsuchida and Yamaguchi, 1977; Zhang and Lang, 1994; Lammers et al, 1996; Weiss et al, 2006; Hurtado et al, 2010). The electrical activity is then propagated distally and gives rise to the mechanical event of peristalsis, ureteral contraction, which propels the bolus of urine distally. Efficient propulsion of the urinary bolus depends on the ureter's ability to completely coapt its walls (Woodburne and Lapidus, 1972). Urine passes into the bladder by way of the ureterovesical junction (UVJ), which, under normal conditions, permits urine to pass from the ureter into the bladder, but not from the bladder into the ureter.

CELLULAR ANATOMY

The primary functional anatomic unit of the ureter is the ureteral smooth muscle cell. The cell is extremely small, approximately 250 to 400 μm in length and 5 to 7 μm in diameter. The nucleus, which is separated from the remainder of the cell by a nuclear membrane, is ellipsoid and contains a darkly staining body, the nucleolus, and the genetic material of the cell. Surrounding the nucleus is the cytoplasm or sarcoplasm, which contains the structures involved in cell function. Frequently in close relation to the nucleus, mitochondria in the cytoplasm perform many of the nutritive functions of the cell. Endoplasmic reticulum or sarcoplasmic reticulum (SR) dispersed in the cytoplasm serves as Ca^{2+} storage sites.

Dispersed in the sarcoplasm are the contractile proteins, actin and myosin. Depending on the local calcium ion (Ca^{2+}) concentration, they interact to produce contraction or relaxation. Any process that leads to a significant increase in the Ca^{2+} concentration in the region of the contractile proteins results in contraction; conversely, any process that leads to a significant decrease in the Ca^{2+} concentration in the region of the contractile proteins results in relaxation. Actin is dispersed throughout the sarcoplasm in hexagonal clumps and is interspersed with the less numerous clumps of more deeply staining myosin. Dark bands along the cell surface are

referred to as *attachment plaques*. Along with dense bodies dispersed in the cytoplasm, they serve as attachment devices for the actin.

Around the periphery of the cell are numerous cavitory structures, some of which open to the outside of the cell and are referred to as *caveolae*. These caveolae contain a cytoskeletal protein, caveolin, and a variety of signal transduction molecules and receptors for growth factors and cytokines (William and Lisanti, 2004). A double-layer cell membrane surrounds the cell. The inner plasma membrane surrounds the entire cell, but the outer basement membrane is absent at areas of close cell-to-cell contact, referred to as *intermediate junctions*.

DEVELOPMENT OF THE URETER

The ureter, a 25- to 30-cm tube extending from the renal pelvis to the bladder, arises as an outpouching from the mesonephric duct. This begins on embryonic day (E) 10.5 in mice and E28 in humans. Signals from the metanephric mesenchyme, stroma, and angioblasts induce the ureteral bud to arise from the mesonephric duct, invade the metanephric mesenchyme, and undergo branching. The nephric (mesonephric or wolffian) duct cells express a number of surface receptors including RET, FGFR, AT2R, and ALK (Fig. 43-1). RET signaling is induced by glial cell line-derived neurotrophic factor (GDNF), derived from adjacent metanephrogenic mesenchyme (Pepicelli et al, 1997; Sainio et al, 1997; Shakya et al, 2005), and leads to a rearrangement of the nephric duct cells (Woolf and Davies, 2013). This movement of cells is regulated by the transcription factors ETV4 and ETV5 (Kuure et al, 2010; Yosypiv, 2014) (see Fig. 43-1). GDNF-RET signaling is a major pathway in the development of the ureter (Woolf and Davies, 2013). GDNF signals through the Ret receptor tyrosine kinase (Vega et al, 1996) and leads to activation of ERK/PI3K/PLC, which results in increased phosphatidylinositol 3-kinase (PI3K) activity and Akt/PKB phosphorylation (Tang et al, 2002). The expression of GDNF and Ret is activated by a transcription factor present in the metanephric mesenchyme, paired box 2 (Pax-2) (Brophy et al, 2001; Clarke et al, 2006), which is increased by AT2 (Zhang et al, 2004). A number of other growth factors including transforming growth factor- β (TGF- β), hepatocyte growth factor (HGF), and fibroblast growth factors (FGFs) FGF-1, FGF-2, FGF-7, and FGF-10; transcription factors including Foxd1, Wnt11, and Spry1; and matrix molecules such as heparan sulfate

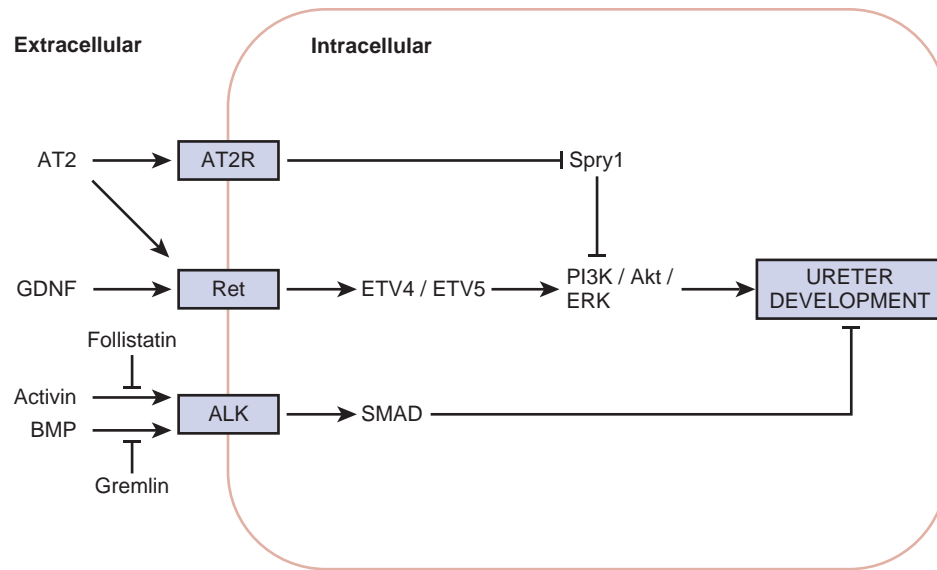

Figure 43-1. Schematic representation of selected pathways involved in ureter development.

proteoglycans, laminins, integrins, and matrix metalloproteinases (MMPs) (e.g., MMP-9) are involved in stimulation or inhibition of growth and branching of the ureteral bud (Davies et al, 1995; Mendelsohn et al, 1999; Qiao et al, 1999; Pohl et al, 2000; Davies, 2001; Qiao et al, 2001; Takemura et al, 2002; Majumdar et al, 2003; Sakurai, 2003; Bush et al, 2004; Chen et al, 2004; Basson et al, 2006).

The nephric ducts also express ALK receptors, which are activated by activins and bone morphogenetic proteins (BMPs) (TGF- β family members), leading to activation of SMADs, which inhibits ureteric bud outgrowth and ureteral development (Mae-shima et al, 2006). Activin A inhibits GDNF-induced ureteral bud formation, and this is accompanied by inhibition of cell proliferation, reduced expression of Pax-2, and decreased phosphorylation of PI3K and mitogen-activated protein (MAP) kinase in the wolffian duct. The tip of each ureteral bud is capable of inducing adjacent metanephric mesenchyme to undergo mesenchymal-to-epithelial transition (MET) with the formation of the nephron (Ekblom, 1989; Shah et al, 2004). Antagonists of the antibranching factors activin and BMP-4 are Gremlin-1 and follistatin, respectively (Woolf and Davies, 2013).

Programmed cell death, or apoptosis, is involved in branching of the ureteric bud and subsequent nephrogenesis. Inhibitors of caspases, which are involved in the apoptotic signaling pathway, inhibit ureteral bud branching (Araki et al, 1999). During development, the ureteral lumen is obliterated, and then it recanalizes (Russo-Gil et al, 1975; Alcaraz et al, 1991). It appears that angiotensin (AT2) acting through the AT2 receptor is involved in the recanalization process (Yerkes et al, 1998) and in the inhibition of aberrant ureteral budding (Oshima et al, 2001). Knockout mice for the *atr2* gene have congenital anomalies of the kidney and urinary tract, including duplicated collecting systems with a hydronephrotic upper pole moiety, multicystic dysplastic kidneys, megaureters, and ureteropelvic junction (UPJ) obstructions. Mutant mice lacking AT2 type 1 receptors fail to develop a renal pelvis and lack ureteral peristaltic activity (Miyazaki et al, 1998). AT2 acting via AT2 type 1 receptors also is involved in ureteric bud cell branching, a process that depends on phosphorylation of the EGF receptor (Iosipiv and Schroeder, 2003; Yosypiv et al, 2006) and can stimulate in vitro branching morphogenesis by directly acting on the ureteric bud (Song et al, 2011). In addition, AT2 induces the expression of the GDNF/c-Ret/Wnt11 pathway and represses Spry1 during ureteric bud branching (Yosypiv et al, 2008; Song et al, 2010). Ureteric branching also is promoted by AT2-induced signaling through PI3K/Akt and ERK (Song et al, 2011; Yosypiv, 2014). Because Spry1

inhibits ERK, this may be one mechanism to enhance c-Ret signaling and stimulate ureteric branching (Yosypiv et al, 2008; Song et al, 2010). Some GDNF targets upregulated by AT2 include transcription factors (Etv4, Etv5), signaling molecules (Vsn11), and receptors (Crlf1) (Song et al, 2011).

Another player in regulating normal ureter development is Brg1 (or SMARCA4). Brg1 is an epigenetic regulator and is part of the switch/sucrose nonfermentable (SWI/SNF) chromatin-remodeling complex. Global loss of Brg1 results in embryonic lethality (Bultman et al, 2000). Brg1 has been shown to be upstream of p63, peroxisome proliferator-activated receptor- γ (PPAR- γ), and sonic hedgehog. Ablation of Brg1 leads to ureter malformation (Weiss et al, 2013).

Calcineurin, a Ca^{2+} -dependent serine/threonine phosphatase, also appears to be an essential signaling molecule in urinary tract development. Mutant mice in which calcineurin function is removed are noted to have reduced proliferation of smooth muscle and mesenchymal cells in the developing urinary tract with abnormal development of the renal pelvis and ureter with resultant defective pyeloureteral peristalsis (Chang et al, 2004).

ELECTRICAL ACTIVITY

The electrical properties of all excitable tissues depend on the distribution of ions on both the inside and the outside of the cell membrane and on the relative permeability of the cell membrane to these ions (Hodgkin, 1958). The ionic basis for electrical activity in ureteral smooth muscle has not been fully described; however, many of its properties resemble those in other excitable tissues.

Resting Potential

When a ureteral muscle cell is in a nonexcited or resting state, the electrical potential difference across the cell membrane, the transmembrane potential, is referred to as the *resting membrane potential* (RMP). The RMP is determined primarily by the distribution of potassium ions (K^+) across the cell membrane and by the permeability of the membrane to K^+ (Hendrickx et al, 1975). In the resting state, the K^+ concentration on the inside of the cell is greater than that on the outside of the cell—that is, K^+_i is greater than K^+_o —and the membrane is preferentially permeable to K^+ . Because of the tendency for the positively charged K^+ ions to diffuse from the inside of the cell, where they are more concentrated, to

the outside of the cell, where they are less concentrated, an electrical gradient is created, with the inside of the cell membrane being more negative than the outside (Fig. 43-2A). The electrical gradient that is formed tends to oppose the further movement of K^+ outward across the cell membrane along its concentration gradient, and an equilibrium is reached.

If the membrane in the resting state were exclusively permeable to K^+ , the measured RMP of the ureteral smooth muscle cell would approximate -90 mV, the K^+ equilibrium potential, as predicted by the Nernst equation:

$$E_k = -RT/nF \ln(K^+)_i / (K^+)_o$$

where E_k is the potential difference attributable to the concentration difference of K^+ across the cell membrane, R is the molar gas constant, T is the absolute temperature, n is the number of moles of K^+ , and F is the Faraday constant (Nernst, 1908). However, in the ureter and in other smooth muscles, the RMP is considerably less than the K^+ equilibrium potential, with values of -33 to -70 mV, the inside of the cell being negative with respect to the outside (Kuriyama et al, 1967). Studies from single isolated ureteral cells show spontaneous transient hyperpolarizations with the RMP transiently becoming more negative (Imaizumi et al, 1989). This phenomenon appears to be the result of spontaneous release of

Ca^{2+} from the SR with activation of tetraethylammonium (TEA) and charybdotoxin-sensitive Ca^{2+} -dependent K^+ channels ($I_{K[Ca]}$). Although the low resting potential of ureteral cells may be explained in part by a relatively small resting K^+ conductance (Imaizumi et al, 1989), it also may be a result of the contribution of other ions.

One such ion that could account for the relatively low RMP of the ureter and other smooth muscles is the sodium ion (Na^+) (Kuriyama, 1963). In the resting state, the Na^+ concentration on the outside of the cell membrane is greater than that on the inside—that is, Na^+_o is greater than Na^+_i . If the resting membrane were somewhat permeable to Na^+ , both the concentration and the electrical gradient would support an inward movement of Na^+ across the cell membrane, with a resultant decrease in the electronegativity of the inner surface of the cell membrane (Fig. 43-2B).

If such an inward movement of Na^+ went unchecked, the RMP would be expected to decrease to a level lower than that actually observed, and the concentration gradient for Na^+ might become reversed. To maintain a steady-state ion distribution across the cell membrane with K^+_o less than K^+_i and Na^+_o greater than Na^+_i and to prevent the transmembrane potential from becoming lower than the measured ureteral RMP, an active mechanism capable of extruding Na^+ from within the cell against a concentration and electrochemical gradient is required (Fig. 43-2C). Such an outward Na^+ pump that is coupled with an inward movement of K^+ derives its energy requirements from the dephosphorylation of adenosine triphosphate (ATP) (Casteels, 1970). Na^+ - Ca^{2+} exchange also may play a role in Na^+ extrusion, especially when the Na^+ pump is inhibited (Aickin, 1987; Aickin et al, 1987; Lamont et al, 1998).

The dynamic processes illustrated in Figure 43-2 enable the ureter in its resting state to maintain a relatively low RMP. In addition to the mechanisms described, the distribution of chloride ions (Cl^-) across the cell membrane and the relative permeability of the membrane to Cl^- may affect the maintenance of the RMP in the ureter and other smooth muscles (Kuriyama, 1963; Washizu, 1966). Activation of Ca^{2+} -activated Cl^- channels ($ClCa$) also can decrease the membrane potential and therefore depolarizes the membrane (Verkman and Galietta, 2009).

Action Potential

The transmembrane potential of an inactive or resting ureteral cell remains stable until it is excited by an external stimulus (electric, mechanical, or chemical) or by conduction of electrical activity (action potential) from an already excited adjacent cell. When a ureteral cell is stimulated, depolarization occurs, with the inside of the cell membrane becoming less negative than it was before stimulation. If a sufficient area of the cell membrane is depolarized rapidly enough to reach a critical level of transmembrane potential, referred to as the **threshold potential**, a regenerative depolarization, or action potential, is initiated.

The changes that occur are diagrammatically depicted in Figure 43-3. If a stimulus is very weak, as shown by arrow *a*, the transmembrane potential may remain unchanged. A slightly stronger, yet subthreshold, stimulus may result in an abortive displacement of the transmembrane potential, but not to such a degree that an action potential is generated (arrow *b*). If the stimulus is strong enough to decrease the transmembrane potential to the threshold potential, the cell becomes excited and produces an action potential (arrow *c*). The action potential, which is the primary event in the conduction of the peristaltic impulse, has the capability to act as the stimulus for excitation of adjacent quiescent cells and through a complicated chain of events gives rise to the ureteral contraction.

When the ureteral cell is excited, its membrane loses its preferential permeability to K^+ and becomes more permeable to Ca^{2+} ions that move inward across the cell membrane primarily through fast L-type Ca^{2+} channels and give rise to the upstroke of the action potential (Fig 43-4A) (Kobayashi, 1965; Kuriyama and Tomita, 1970; Imaizumi et al, 1989; Lang, 1989, 1990; Sui and Kao, 1997a, 1997b; Smith et al, 2002). L-type Ca^{2+} channels are inhibited by the calcium channel blocker nifedipine and by

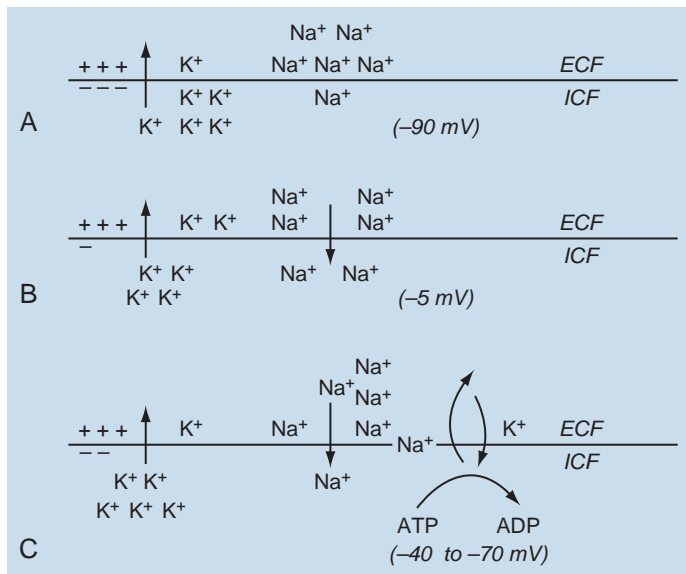

Figure 43-2. Ionic basis for the resting membrane potential (RMP) in smooth muscle. In the resting state, the K^+ concentration inside the cell is greater than the K^+ concentration outside the cell, and the Na^+ concentration outside the cell is greater than the Na^+ concentration inside the cell. A, Electrochemical changes that would occur if the membrane were solely permeable to potassium. Potassium would diffuse from the inside of the cell, where it is more concentrated, to the outside of the cell, where it is less concentrated. The outward movement of the positively charged K^+ ions would make the inside of the cell membrane negative with respect to the outside of the cell membrane. B, Electrochemical changes that would occur if the resting membrane were also permeable to sodium. An inward movement of Na^+ along its concentration gradient would make the inside of the cell membrane less negative with respect to the outside of the cell membrane than is depicted in A. C, Pump mechanism for extruding Na^+ from within the cell against concentration and electrochemical gradients. Inward movement of K^+ is coupled with outward movement of Na^+ . This mechanism helps to maintain a steady state of ion distribution across the cell membrane and a stable RMP. ECF, extracellular fluid; ICF, intracellular fluid. (From Weiss RM. Ureteral function. *Urology* 1978;12:114.)

cadmium (Cd^{2+}) and are potentiated by barium (Ba^{2+}). As the positively charged Ca^{2+} ions move inward across the cell membrane, the inside of the membrane becomes less negative with respect to the outside and may even become positive at the peak of the action potential, a state referred to as *overshoot*. Na^{+} ions also may play a role in the upstroke of the ureteral action potential (Kobayashi, 1964, 1965; Muraki et al, 1991). The rate of rise of the upstroke of the ureteral action potential is relatively slow, 1.2 ± 0.06 V/sec in the cat (Kobayashi, 1969). This compares with a 610 V/sec rate of rise in dog cardiac Purkinje fibers (Draper and Weidmann, 1951) and a 740 V/sec rate of rise in skeletal muscle (Ferroni and Bianchi,

1965). The slow rate of upstroke rise of the ureteral action potential accounts for the slow conduction velocity in the ureter.

After reaching the peak of its action potential, the ureter maintains its potential for a period of time (plateau of the action potential) before the transmembrane potential returns to its resting level (repolarization) (Kuriyama et al, 1967). The plateau phase of the guinea pig action potential is superimposed with multiple oscillations, a phenomenon not observed in the rat, rabbit, or cat (Fig. 43-5) (Bozler, 1938). The plateau phase appears to depend on the persistence of an inward Ca^{2+} current and on Na^{+} influx through a voltage-dependent Na^{+} channel (see Fig 43-4A) (Kuriyama and Tomita, 1970; Imaizumi et al, 1989; Sui and Kao, 1997a). Also involved in the plateau formation is the maintenance of depolarization by an inward calcium-dependent chloride current ($I_{\text{Cl}(\text{Ca})}$) which is countered by outward voltage-gated and Ca^{2+} -activated K^{+} currents (K_{Ca}) (Smith et al, 2002). There are species differences in the ionic currents involved in the formation of the action potential, with the Ca^{2+} -activated chloride current being present in the rat but not in the guinea pig ureter. The inward Cl^{-} current can be inhibited by niflumic acid and by Ba^{2+} (Smith et al, 2002). The oscillations on the plateau of the guinea pig action potential appear to depend on the repetitive activation of an inward Ca^{2+} current (Kuriyama and Tomita, 1970) and of a Ca^{2+} -dependent outward K^{+} current (Imaizumi et al, 1989). Prolongation of the inward calcium current and the duration of the action potential correlates with an increased force of contraction (Burdyga and Wray, 1999b).

The activation of a Ca^{2+} -dependent K^{+} current that is involved in repolarization is mainly a result of Ca^{2+} release from the endoplasmic reticulum that is triggered by the influx of extracellular Ca^{2+} through voltage-dependent Ca^{2+} channels. The increase in intracellular Ca^{2+} concentration during the upstroke and plateau of the action potential finally may activate the outward Ca^{2+} -dependent K^{+} current ($I_{\text{K}(\text{Ca})}$) to such a degree that repolarization occurs with return of the transmembrane potential to its resting level (see Fig 43-4A) (Imaizumi et al, 1989; Sui and Kao, 1997c). The $I_{\text{K}(\text{Ca})}$ is sensitive to inhibition by TEA. TEA increases the amplitude and duration of in vitro ureteral contractions (Floyd et al, 2008). A voltage-dependent, Ca^{2+} insensitive outward K^{+} current (I_{TO}) also

Figure 43-3. Response of ureteral transmembrane potential to stimuli. At arrow a, a weak stimulus is applied that does not alter the resting membrane potential (MP). At arrow b, a stimulus is applied that decreases the transmembrane potential but not to the level of the threshold potential (TP) (subthreshold stimulus). At arrow c, a stimulus is applied that decreases the transmembrane potential to TP, and an action potential is initiated (suprathreshold stimulus). (From Weiss RM. Ureteral function. *Urology* 1978;12:114.)

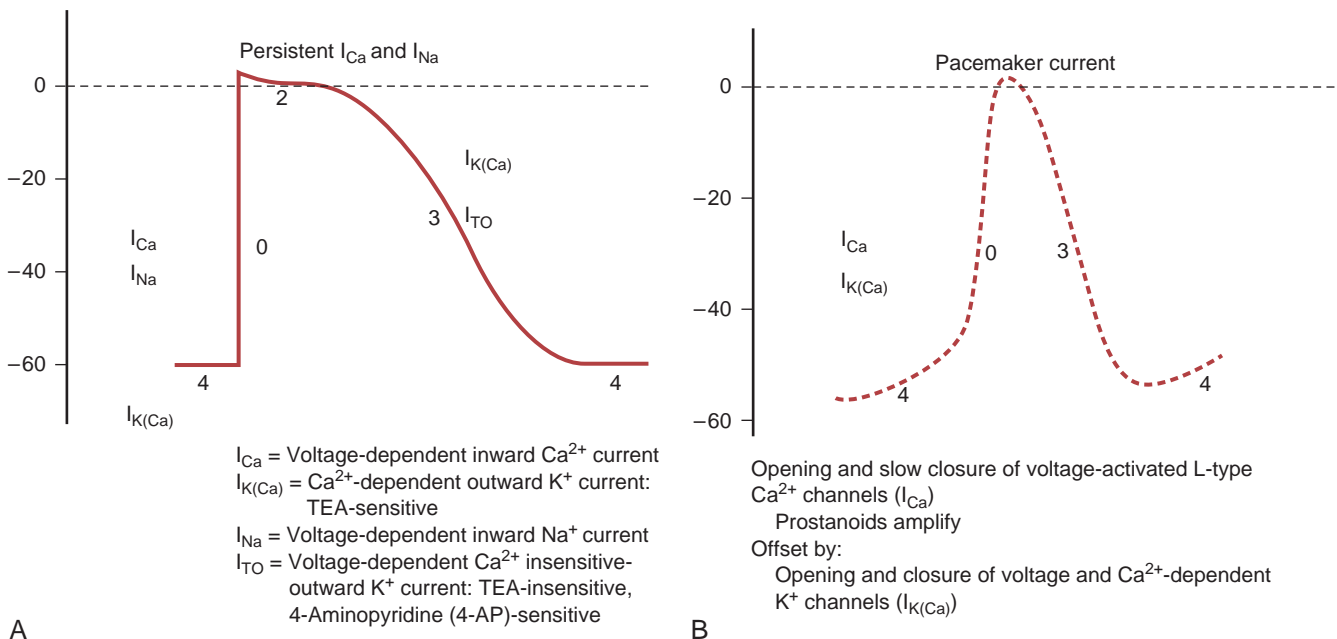

Figure 43-4. Schematic representation of ionic currents in A, nonpacemaker (solid line) and B, pacemaker (dashed line) action potentials: 0, upstroke or depolarization phase; 2, plateau phase; 3, repolarization phase; and 4, resting potential of the nonpacemaker cell and spontaneous depolarization phase of the pacemaker cell. A spontaneous decrease in the transmembrane potential of pacemaker cells accounts for their spontaneous activity. TEA, tetraethylammonium.

Figure 43-5. Intracellular recordings of ureteral action potentials (*upper tracings*) and isometric recordings of contractions (*lower tracings*) in response to electric stimuli. Action potentials precede contractions. **A**, Guinea pig ureter; oscillations on the plateau of the action potential. **B**, Cat ureter; no oscillations on the plateau of the action potential. (From Weiss RM. Ureteral function. *Urology* 1978;12:114.)

appears to be involved in the repolarization (Lang, 1989; Imaizumi et al, 1990). These currents are TEA insensitive and 4-aminopyridine (4-AP) sensitive. In the rat but not the guinea pig ureter there is a late TEA-, Cd^{2+} -, and Ca^{2+} -insensitive outward K^+ current that also is involved in the repolarization process. The duration of the action potential in the cat ranges from 259 to 405 msec (Kobayashi and Irisawa, 1964).

In summary, the RMP of the ureteral cell is approximately -33 to -70 mV and is determined primarily by the distribution of K^+ ions across the cell membrane and the relatively selective permeability of the resting cell membrane to K^+ . When excited by a suprathreshold stimulus, the membrane becomes less permeable to K^+ and more permeable to Ca^{2+} , which moves inward across the cell membrane and provides the ionic mechanism for the development of the upstroke of the action potential. After reaching the peak of its action potential, the membrane maintains a depolarized state—plateau of the action potential—for a period of time before the membrane potential of the activated cell returns to its resting level (repolarization). The plateau appears to be related to a persisting inward Ca^{2+} current and to an influx of Na^+ . Repolarization of the membrane is related to a renewed increase in permeability to K^+ .

Pacemaker Potentials and Pacemaker Activity

Electrical activity arises in a cell either spontaneously or in response to an external stimulus. If the activity arises spontaneously, the cell is referred to as a *pacemaker cell*. Pacemaker cells differ from nonpacemaker cells in that their transmembrane resting potential is lower (less negative) than that of nonpacemaker cells (Lang and Zhang, 1996) and does not remain constant but rather undergoes a slow spontaneous depolarization (see Fig. 43-4B). If the spontaneously changing membrane potential reaches the threshold potential, the upstroke of an action potential occurs. The ionic conduction underlying pacemaker activity in the upper urinary tract is caused by the opening and slow closure of voltage-activated L-type Ca^{2+} channels (Santicioli et al, 1995a). This is opposed by the opening and closure of voltage- and Ca^{2+} -dependent K^+ channels. It has been suggested that prostaglandins (PGs) and excitatory tachykinins released from sensory nerves help maintain autorhythmicity in the upper urinary tract through maintenance of Ca^{2+} mobilization (Lang et al, 2002a). Tetrodotoxin and blockers of the autonomic nervous system, both parasympathetic and sympathetic, have little effect on peristalsis, suggesting that autonomic neurotransmitters have little role in maintaining pyeloureteral motility (Lang et al, 2001, 2002b). Changes in the

frequency of action potential development may result from a change in the level of the threshold potential, a change in the rate of slow spontaneous depolarization of the resting potential, or a change in the level of the resting potential.

Gosling and Dixon (1971, 1974) provided morphologic evidence of specialized pacemaker tissue in the proximal portion of the urinary collecting system and described species differences. In species with a multicalyceal system, such as the pig, sheep, and human, the pacemaker cells are located near the pelvicalyceal border (Dixon and Gosling, 1973). In species with an unicalyceal system, such as the dog, cat, rat, rabbit, and guinea pig, the pacemaker cells extend from the pelvicalyceal border to the UPJ. These atypical smooth muscle cells that give rise to pacemaker activity, in contrast to typical smooth muscle cells, have less than 40% of their cellular area occupied by contractile elements and demonstrate sparse immunoreactivity for smooth muscle and actin (Klemm et al, 1999; Lang et al, 2001). These atypical smooth muscle spindle-shaped cells are 90 to 230 μm in length, and their electrical activity consists of simple waveforms of alternating depolarizing and repolarizing phases that occur at a relatively rapid frequency of 8 to 15 per minute (Fig. 43-6A) (Tsuchida and Suzuki, 1992; Klemm et al, 1999). Pacemaker potentials have a lower RMP, a slower rate of rise, and a lower amplitude than action potentials recorded from nonpacemaker cells. In the guinea pig these atypical, presumably pacemaker, cells comprise more than 80% of the cells at the pelvicalyceal junction and about 15% of the cells in the proximal renal pelvis but are not present in the distal renal pelvis or ureter (Klemm et al, 1999). Electrical recordings correlate with histologic findings in that pacemaker potentials were not observed in the distal renal pelvis or ureter (Klemm et al, 1999).

Driven action potentials that fire at lower frequency (three to five per minute) than pacemaker potentials are recorded from longer (150 to 400 μm) spindle-shaped typical smooth muscle cells (Fig. 43-6B) (Klemm et al, 1999). Most muscle cells of the ureter (100%), distal renal pelvis (97.5%), and proximal renal pelvis (83%) are typical nonpacemaker smooth muscle cells with typical action potentials. Lang and colleagues (1998) described fibroblast-like cells resembling the interstitial cells of Cajal (ICCs), which serve as pacemaker cells in the intestine, in the proximal portion of the guinea pig renal pelvis. These ICC-like cells are irregularly shaped with oval nuclei and many branching interconnecting processes and contain numerous mitochondria, caveolae, and prominent endoplasmic reticulum. The ICC-like cells in the guinea pig are not immunoreactive for α -smooth muscle actin (α -SMA), which is present in typical smooth muscle cells, or for c-KIT, a tyrosine kinase receptor that is expressed in intestinal ICC pacemaker cells (Klemm

Figure 43-6. Action potentials in the upper urinary tract of the guinea pig. **A**, Pacemaker potentials. **B**, Driven action potentials. **C**, Intermediate action potentials. (Modified from Klemm MF, Exintaris B, Lang RJ. Identification of the cells underlying pacemaker activity in the guinea pig upper urinary tract. *J Physiol* 1999;519:867.)

et al, 1999). The immunoreactivity to c-KIT appears to be species specific because ICC-like cells that are immunoreactive to antibodies raised against the *c-KIT* proto-oncogene are present in the upper urinary tract of a number of mammals (Lang and Klemm, 2005; Metzger et al, 2005). Electrical recordings from these cells demonstrate action potentials with properties intermediate to pacemaker and driven action potentials. Intermediate action potentials in the guinea pig have a single spike, a plateau without the superimposed spikes seen in driven action potentials, and a rapid repolarization phase (Fig. 43-6C). Intermediate action potentials are noted in 11% to 17% of cells at the pelvicalyceal junction and the proximal and distal renal pelvis (Lang et al, 2002b). These ICC-like cells in the upper urinary tract do not appear to be primary pacemaker cells but rather may provide for preferential conduction of electrical signals from pacemaker cells to typical smooth muscle cells of

the renal pelvis and ureter (Klemm et al, 1999). In the mouse UPJ, c-KIT-positive ICC-like cells have been identified that show high-frequency spontaneous transient inward currents (STICs) that often occur in bursts and sum to produce long-lasting large inward currents (Lang et al, 2007b). It is postulated that in the absence of a proximal pacemaker, these ICC-like cells could act as pacemaker cells and trigger contractions in adjacent smooth muscle cells in the UPJ. Thus, both atypical smooth muscle cells and ICC-like cells may play a pacemaker role in the initiation and propagation of pyeloureteric peristalsis (Lang et al, 2006; Lang et al, 2007a).

c-KIT is a tyrosine kinase receptor that promotes cell migration and proliferation of melanoblasts, hematopoietic progenitors, and primordial germ cells. Mice expressing mutant inactivating c-KIT alleles lack intestinal ICCs and have abnormal intestinal peristalsis and develop bowel obstruction, showing that c-KIT is important in the development of pacemaker activity and peristalsis of the gut (Der-Silaphet et al, 1998). Pezzone and colleagues (2003) identified c-KIT-positive cells in the mouse ureter. They suggested that the difference from previous studies in the guinea pig upper urinary tract in which c-KIT positivity was not identified in ICC-like cells (Klemm et al, 1999) may have been caused by species differences, the c-KIT antibody used, and/or the fixation methods. c-KIT expression was noted to be upregulated in the embryonic murine ureter before its development of unidirectional peristaltic contractions (David et al, 2005). Incubation of isolated cultured embryonic murine ureters with antibodies that neutralize c-KIT activity altered ureteral morphology and inhibited unidirectional peristalsis. These data suggest that c-KIT-containing cells, which are most probably ICC-like cells, have an important role in pyeloureteric peristalsis. c-KIT-positive cells have been identified in the human ureter (Metzger et al, 2004; van der Aa et al, 2004) and in the human UPJ (Solari et al, 2003). In the presence of obstruction, c-KIT-positive ICC-like cells at the UPJ have been reported to be decreased (Solari et al, 2003; Yang et al, 2009) or increased (Koleda et al, 2012).

More recently, hyperpolarization-activated cation-3 (HCN3) channels were shown to be expressed at the pelvis-kidney junction and to play a role in the development of pacemaker activity. Uncoordinated peristalsis was demonstrated in renal pelvis-ureter explants that were treated with an HCN3 channel blocker (Hurtado et al, 2010). Furthermore, it has been shown that hedgehog signaling controls KIT and HCN3 expression and that the hedgehog signaling pathway is required for the development of pacemaker function and coordinated peristalsis in the mouse ureter (Cain et al, 2011). Inhibition of either c-KIT or HCN3 results in impaired ureteral peristaltic activity, suggesting that both are required for normal ureteral function.

Bolzler (1942), using small extracellular surface electrodes, demonstrated the characteristic slow spontaneous depolarization of pacemaker-type fibers in the proximal portion of the isolated ureter of a unicalyceal upper collecting system. In a multicalyceal kidney, Morita and associates (1981), using extracellular electrodes, recorded low-voltage potentials that appeared to be pacemaker potentials from the border of the pig minor calyces and the major calyx, with the contraction rhythm varying between each calyx. Multiple pacemakers fire simultaneously as coupled oscillators or individually as pacemaker activity shifts from one site to another along the renal pelvis of the unicalyceal kidney or the pelvicalyceal border of the multicalyceal pig and sheep kidney (Golenhofen and Hannappel, 1973; Constantinou et al, 1977; Constantinou and Yamaguchi, 1981; Lammers et al, 1996).

Although the primary pacemaker for ureteral peristalsis is located in the proximal portion of the collecting system, other areas of the ureter may act as latent pacemakers. Under normal conditions, the latent pacemaker regions are dominated by activity arising at the primary pacemaker sites. When the latent pacemaker site is freed of its domination by the primary pacemaker, it, in turn, may act as a pacemaker. To demonstrate latent pacemaker sites, Shiratori and Kinoshita (1961) transected the in vivo dog ureter at various levels. Before transection, peristaltic activity arose proximally from the primary pacemaker. When the ureter was transected at the

UPJ, antiperistaltic waves of lower frequency than the previous normoperistaltic waves originated from the UVJ. Division of the ureter at the UVJ did not affect the normoperistaltic waves. After division of the mid-ureter, the normoperistaltic waves in the upper segment remained unchanged, and the lower segment demonstrated antiperistaltic waves, which originated at the UVJ at a frequency less than that of the normoperistaltic waves in the upper segment. Thus, cells at the UVJ of the dog may act as pacemaker cells when freed of control from the primary proximally located pacemaker. Latent pacemaker cells are present throughout the ureter (Imaizumi et al, 1989; Meini et al, 1995).

Propagation of Electrical Activity

Excitable cells possess resistive and capacitive membrane properties similar to those of a cable or core conductor. The transverse resistance of the membrane is higher than the longitudinal resistance of the extracellular or intracellular fluid; this allows current resulting from a stimulus to propagate along the length of the fibers. The spread of current is referred to as *electrotonic spread* (Hoffman and Crane, 1960). The space constant (λ) determines the degree to which the electrotonic potential dissipates with increasing distance from an applied voltage. In a cable, this relation is expressed by

$$P = P_0 e^{-X/\lambda}$$

where X is the distance from the applied voltage, P is the displacement of the membrane potential at X , P_0 is the displacement of the membrane potential at the site of the applied voltage, e is the base of the natural logarithm, and λ is the space constant. Thus, the electrotonic potential decreases by $1/e$ in one space constant. The space constant of the guinea pig ureter as measured by extracellular stimulation is 2.5 to 3 mm (Kuriyama et al, 1967).

The time constant τ_m is expressed by

$$\tau_m = RC$$

where R is the membrane resistance and C is the membrane capacity. The time constant τ_m signifies that a small displacement of potential is decreased by $1/e$ of its value in one τ_m . The time constant of the guinea pig ureter as measured by extracellular stimulation is 200 to 300 msec (Kuriyama et al, 1967).

The ureter acts as a **functional syncytium**. Engelmann (1869, 1870) showed that stimulation of the ureter produces a contraction wave that propagates proximally and distally from the site of stimulation. Under normal conditions, electrical activity arises proximally and is conducted distally from one muscle cell to another across areas of close cellular apposition referred to as *intermediate junctions* (Uehara and Burnstock, 1970; Libertino and Weiss, 1972). The similarity of these close cellular contacts to nexuses, which have been shown to be low-resistance pathways for cell-to-cell conduction in other smooth muscles (Barr et al, 1968), suggests that a similar mechanism for conduction may be present in the ureter. Gap junctions consisting of groups of channels in the plasma membrane of adjacent smooth muscle cells enable exchange of ions and small molecules and play a role in electrical coupling between adjacent cells and in electromechanical coupling (Gabella, 1994; Santicoli and Maggi, 2000). 18 β -glycyrrhetic acid, a gap junction inhibitor, inhibits cell-to-cell electrical coupling in guinea pig renal pelvis and ureter and dissociates electrical and mechanical events (Santicoli and Maggi, 2000). Conduction velocity in the ureter is 2 to 6 cm/sec (Kobayashi, 1964; Kuriyama et al, 1967); it has been shown to vary with temperature, the time interval between stimuli (van Mastriigt et al, 1986), and the pressure within the ureter (Tsuchiya and Takei, 1990). This is in comparison to conduction velocities ranging from 1.5 to 2 m/sec in cardiac Purkinje fibers (Rosen et al, 1981) and from 10 to 100 m/sec in the dorsal and ventral roots of the spinal cord (Biscoe et al, 1977). Conduction in the ureter is similar to that in cardiac tissue, even to the extent that the Wenckebach

phenomenon (a partial conduction block) has been demonstrated in the ureter as it has been in specialized cardiac fibers (Weiss et al, 1968).

CONTRACTILE ACTIVITY

The contractile event is dependent on the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins, actin and myosin. Any process that results in a significant increase in Ca^{2+} in the region of the contractile proteins favors the development of a contraction; any process that results in a significant decrease in Ca^{2+} in the region of the contractile proteins favors relaxation (Fig. 43-7).

Contractile Proteins

In skeletal muscle, Ca^{2+} appears to act as a derepressor. It is thought that in the relaxed state, a regulator system, consisting of the proteins troponin and tropomyosin, prevents the interaction of actin and myosin. In the relaxed state, the troponin that is attached to the tropomyosin is inactive, and the tropomyosin prevents the interaction between actin and myosin. With activation, there is an increase in the sarcoplasmic Ca^{2+} concentration. The Ca^{2+} binds to the troponin, producing a conformational change that results in the displacement of tropomyosin, thus allowing interaction of actin and myosin and the development of a contraction.

In smooth muscle, on the other hand, Ca^{2+} appears to act as an activator. The most widely accepted theory suggests that phosphorylation of myosin is involved in the contractile process and that a troponin-like system does not constitute the primary regulatory mechanism, as it does in skeletal and cardiac muscle. With

Figure 43-7. Schematic representation of calcium ion movements during contraction and relaxation. SR, sarcoplasmic reticulum.

excitation, there is a transient increase in the sarcoplasmic Ca^{2+} concentration from its steady-state concentration of 10^{-8} to 10^{-7} M to a concentration of 10^{-6} M or higher. At this higher concentration, Ca^{2+} forms an active complex with the Ca^{2+} -binding protein calmodulin (Watterson et al, 1976; Cho et al, 1988). Calmodulin without Ca^{2+} is inactive (Fig. 43-8). The Ca^{2+} -calmodulin complex activates a calmodulin-dependent enzyme, myosin light-chain kinase (see Fig. 43-8). The activated myosin light-chain kinase, in turn, catalyzes the phosphorylation of the 20,000-Da light chain of myosin (Fig. 43-9). Phosphorylation of the myosin light chain allows actin to activate myosin Mg^{2+} -ATPase activity, leading to hydrolysis of ATP and the development of smooth muscle tension or shortening (Fig. 43-10). Actin cannot activate the ATPase activity of the dephosphorylated myosin light chain.

When the Ca^{2+} concentration in the region of the contractile proteins is low, the myosin light-chain kinase is not active, because calmodulin requires Ca^{2+} to activate the enzyme. This prevents activation of the contractile apparatus, because the myosin light chain cannot be phosphorylated, a process that must precede tension development. Furthermore, a phosphatase dephosphorylates the myosin light chain, thus preventing actin activation of myosin ATPase activity, and relaxation results.

Evidence indicates that phosphorylation of the enzyme myosin light-chain kinase by a cyclic adenosine monophosphate (cAMP)-dependent protein kinase decreases myosin light-chain kinase activity by decreasing the affinity of this enzyme for calmodulin (Adelstein et al, 1981).

Although Ca^{2+} is required for most smooth muscle contractile events, there is evidence that Ca^{2+} -independent contractions can occur (Yoshimura and Yamaguchi, 1997). Carbachol, a muscarinic cholinergic agonist, and phorbol ester, which activates protein kinase C (PKC), can induce contraction in Ca^{2+} -depleted bladder strips that can be inhibited by a PKC inhibitor, H7. It is suggested that activation of PKC coupled with agonist stimulation of the muscarinic receptor can induce a Ca^{2+} -independent contraction.

Figure 43-8. Schematic representation of the contractile process in smooth muscle. Calmodulin is activated by Ca^{2+} . The activated calcium-calmodulin complex activates the enzyme myosin light-chain kinase, which phosphorylates the light chain of myosin. Phosphorylation of myosin light-chain kinase decreases the rate of activation of the enzyme by the Ca^{2+} -calmodulin complex. cAMP, cyclic adenosine monophosphate.

Calcium and Excitation-Contraction Coupling

The mechanical event of ureteral peristalsis follows an electrical event to which it is related. The Ca^{2+} involved in the ureteral contraction is derived from two main sources. Because smooth muscle cells have a very small diameter, the inward movement of extracellular Ca^{2+} into the cell through L-type voltage-dependent Ca^{2+} channels during the upstroke of the action potential provides a significant source of sarcoplasmic Ca^{2+} (Brading et al, 1983; Hertle and Nawrath, 1989; Yoshida et al, 1992; Maggi et al, 1994a; Maggi and Giuliani, 1995; Floyd et al, 2008) (see Fig. 43-7). This inward movement of Ca^{2+} across the cell membrane is the major source of calcium used for contraction in most smooth

Figure 43-9. Schematic representation of the contractile process in smooth muscle. The activated enzyme myosin light-chain kinase catalyzes the phosphorylation of myosin. Myosin must be phosphorylated for actin to activate myosin adenosine triphosphatase. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Figure 43-10. Schematic representation of the contractile process in smooth muscle. Actin activates adenosine triphosphatase activity of phosphorylated myosin. This allows interaction of actin and myosin with the development of a contraction. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

muscles. $\text{Na}^+\text{-Ca}^{2+}$ exchange, with an outward movement of Na^+ and an inward movement of Ca^{2+} , also plays a role in the ureteral contraction (Lamont et al, 1998). Furthermore, in response to an excitatory impulse, Ca^{2+} release from tightly bound storage sites (e.g., the endoplasmic reticulum or SR) also increases the Ca^{2+} concentration in the sarcoplasm (Burdyga et al, 1998, 1999a; Lang et al, 2002b). Calcium may be released from the SR of smooth muscle by an inositol 1,4,5-trisphosphate (IP_3)-induced release mechanism or by Ca^{2+} -induced Ca^{2+} release (CICR) (Somlyo and Somlyo, 1994). These processes appear to be species dependent. CICR, which involves ryanodine receptors, appears to be the sole mechanism for calcium release from the SR in the guinea pig ureter, whereas the SR store in the rat ureter appears to be exclusively under the control of IP_3 receptors (Burdyga et al, 1995). IP_3 and ryanodine receptors are expressed in the human ureter (Floyd et al, 2008). The opening of caffeine-sensitive ryanodine receptors produces small local elevations of Ca^{2+} that are termed *Ca^{2+} sparks* (Nelson et al, 1995). In addition to providing a source of calcium for contraction, Ca^{2+} released from the SR activates Ca^{2+} -sensitive surface membrane channels and modulates membrane excitability (Imaizumi et al, 1989; Carl et al, 1996). Both calcium-activated outward potassium currents (K_{Ca}) or spontaneous transient outward currents (STOCs) and calcium-activated inward chloride currents (Cl_{Ca}) or STICs have been identified in smooth muscles. These currents affect membrane potential and thus affect calcium entry through L-type Ca^{2+} channels in the membrane. The Ca^{2+} -activated chloride currents are present in rat but not guinea pig ureteral smooth muscle (Burdyga and Wray, 2002). Thus, some Ca^{2+} released from SR results in contraction, but caffeine-induced release of SR Ca^{2+} in the form of Ca^{2+} sparks increases outward potassium currents (K_{Ca}) or STOCs with an inhibitory effect on action potentials and contractility (Borisova et al, 2007). At least in the guinea pig ureter, this increase in the outward potassium current hyperpolarizes the membrane and determines the refractory period, which is important in determining the frequency of ureteral peristalsis (Burdyga and Wray, 2005).

Support for use of a dual source of Ca^{2+} in the ureter has been provided by Vereecken and coworkers (1975), who noted that it took approximately 45 minutes for spontaneous contractions of isolated guinea pig ureters to cease when the tissue was placed in a Ca^{2+} -free medium. They interpreted this to indicate that some of the Ca^{2+} involved in the contractile process is derived from tightly bound intracellular stores. They also noted that recovery of the contractile response to electric stimuli was almost immediate when the tissue was returned to a physiologic solution containing a normal concentration of Ca^{2+} . This suggests that free extracellular Ca^{2+} entering the cell during excitation also provides a source of Ca^{2+} for the contractile machinery. A similar conclusion was reached by Hong and associates (1985). There is, however, some evidence in ureteral contractions, at least in the guinea pig (Maggi et al, 1994a, 1995, 1996), and some perturbations of contractility may be related to movements of ions other than Ca^{2+} . The increase in developed force in the guinea pig ureter with intracellular acidification and decrease with intracellular alkalization appear to result from modulation of outward K^+ currents rather than effects on inward Ca^{2+} currents (Smith et al, 1998). That is, alkalization (increasing intracellular pH) enhances outward K^+ currents and this reduces excitability; acidification has the opposite effect. Relaxation results from a decrease in the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins. The decrease in sarcoplasmic Ca^{2+} can result from the uptake of Ca^{2+} into intracellular storage sites (Maggi et al, 1994a, 1995) or from extrusion of Ca^{2+} from the cell (Burdyga and Magura, 1988).

In addition to the Ca^{2+} -signaling cascade that affects contractility, there is a Rho/Rho-kinase signaling pathway that affects contractility by altering the Ca^{2+} sensitivity of the contractile system (Somlyo and Somlyo, 2003). The Rho-kinase pathway is involved in ureteral contractions in a number of species (Levent and Buyukafsar, 2004; Shabir et al, 2004; Hong et al, 2005). RhoA, a small GTP binding protein, binds to Rho-kinase and causes its migration to the cell

membrane, where it becomes maximally active (Leung et al, 1995; Ishizaki et al, 1996). Rho-kinase inhibits myosin phosphatase by phosphorylation of its regulatory subunit, which prevents dephosphorylation of myosin light chain, which in turn leads to Ca^{2+} sensitization of the smooth muscle with subsequent increase in contractility. Y-27632, an inhibitor of Rho-kinase, decreases both spontaneous and electric field stimulation (EFS)-induced contractile responses of in vitro rat and human ureteral segments without causing changes in calcium (Shabir et al, 2004; Hong et al, 2005). **Activation of Rho-kinase affects smooth muscle contractility without causing changes in calcium.**

Urothelial Effects on Contractile Activity

Furchgott (1999) showed in blood vessels that the endothelium produced a factor that had a relaxing action on the smooth muscle layer of the blood vessel. This factor was originally termed *endothelium-derived relaxing factor* (EDRF) and was subsequently shown to be nitric oxide (NO). Mastrangelo and colleagues (2003) showed that the urothelium of rat ureter produced NO, which inhibited contractile responses of the rat ureter. It was shown that the urothelium inhibited spontaneous contractions of isolated rat ureteral segments and that removal of the urothelium potentiated the stimulatory effects of neurokinin A, vasopressin, carbachol, bradykinin, and AT2 (Mastrangelo and Iselin, 2007). In intact ureteral segments cyclooxygenase (COX) inhibitors potentiated the stimulatory effects of neurokinin A, vasopressin, carbachol, bradykinin, and angiotensin II. COX inhibitors had no effect on the responses to these agents in urothelium-free ureters. These data suggest that the inhibitory effects of the urothelium on ureteral contractile events may involve the participation of a urothelial COX product such as prostacyclin.

Second Messengers

The functional response to a number of hormones, neurotransmitters, and other agents is mediated by *second messengers*. The agonist, or first messenger, interacts with a specific membrane-bound receptor (Alquist, 1948; Furchgott, 1964); the agonist-receptor complex then activates or inactivates an enzyme that leads to alteration of the amount of a second messenger within the cell. These **second messengers include cAMP, cyclic guanosine monophosphate (cGMP), Ca^{2+} , IP_3 , and diacylglycerol (DG)**. They mediate the functional response to the agonist (first messenger) through a process that frequently involves protein phosphorylation.

cAMP is believed to mediate the relaxing effects of β -adrenergic agonists in a variety of smooth muscles (Triner et al, 1971; Andersson, 1972; Vesin and Harbon, 1974). According to this concept, a β -adrenergic agonist, such as isoproterenol, serves as the first messenger and combines with a receptor on the outer surface of the cell membrane (Fig. 43-11). Isoproterenol itself does not enter the cell. The **β -adrenergic agonist-receptor** complex activates the enzyme adenylyl cyclase on the inner surface of the cell membrane in close morphologic relation to the receptor. **In the presence of magnesium (Mg^{2+}) and a guanine nucleotide (GTP), adenylyl cyclase catalyzes the conversion of ATP to cAMP within the cell.**

A **stimulatory guanine nucleotide-regulatory protein, or G protein (G_s)**, acts as a functional communication between the agonist-receptor complex and the catalytic or active unit of the enzyme adenylyl cyclase. cAMP acts as a second, or “internal,” messenger of the response elicited by the β -adrenergic agonist. It has been suggested that the increase in cAMP through activation of an enzyme—that is, a protein kinase—and phosphorylation of proteins leads to the uptake of Ca^{2+} into intracellular storage sites (i.e., the endoplasmic reticulum or SR) with the resultant decrease of free sarcoplasmic Ca^{2+} in the region of the contractile proteins (Andersson and Nilsson, 1972). The decrease in sarcoplasmic Ca^{2+} in the

Figure 43-11. Schematic representation of the role of cyclic adenosine monophosphate (cAMP) in β -adrenergic agonist-induced relaxation of smooth muscle. Agonist combines with receptor on the outer side of the cell membrane. The receptor-agonist complex, in turn, via a stimulatory G protein, G_s , activates the enzyme adenylyl cyclase (AC) on the inner surface of the cell membrane, which in the presence of Mg^{2+} guanosine triphosphate (GTP) results in the conversion of adenosine triphosphate (ATP) to cAMP. cAMP is postulated to cause an increased uptake of Ca^{2+} into intracellular storage sites with a resultant decrease in Ca^{2+} in the region of the contractile proteins, which results in relaxation. cAMP may also have other actions (not shown) that inhibit the contractile process. The enzyme phosphodiesterase (PDE) degrades cAMP to 5'-AMP. SR, sarcoplasmic reticulum.

region of the contractile proteins leads to relaxation of the smooth muscle. β -Adrenoceptor-induced relaxation of smooth muscle also may be caused by the opening of Ca^{2+} -activated K^+ channels (Uchida et al, 2005; Ferro, 2006).

cAMP levels may be increased within the cell in two ways. One is by increasing synthesis, which involves activation of the enzyme adenylyl cyclase; the other is by decreasing degradation. The degradation of cAMP involves activation of an enzyme, phosphodiesterase (PDE):

Thus agents that either increase adenylyl cyclase activity, such as the β -adrenergic agonist isoproterenol, or decrease PDE activity, that is, phosphodiesterase inhibitors such as theophylline and papaverine, increase intracellular cAMP levels and cause smooth muscle relaxation.

Weiss and associates (1977) demonstrated the presence of both adenylyl cyclase and PDE activities in the ureter. They showed in the ureter that isoproterenol stimulates adenylyl cyclase activity and theophylline inhibits PDE activity. These two agents, which relax ureteral smooth muscle, would be expected to increase cAMP levels—*isoproterenol* by increasing synthesis and *theophylline* by decreasing degradation. Further support of a role for cAMP in smooth muscle relaxation can be derived from the findings that dibutyryl cAMP, which more readily diffuses into the intact cell and is less likely to be broken down by PDE than is cAMP, has been shown to relax a variety of smooth muscles, including the ureter (Takago et al, 1971; Wheeler et al, 1990) and that forskolin, which activates the catalytic subunit of adenylyl cyclase, relaxes the ureter (Wheeler et al, 1986; Hernández et al, 2004).

In addition to receptors and G proteins that are involved in stimulation of adenylyl cyclase and the formation of cAMP, as in the actions of β -adrenergic agonists, other receptors and G proteins inhibit adenylyl cyclase activity (Londos et al, 1981). Some actions of α_2 -adrenergic and muscarinic cholinergic agonists

Figure 43-12. Schematic representation of inducible and constitutive nitric oxide synthase (NOS). CaM, calmodulin; cGMP, cyclic guanosine monophosphate; GC, guanylyl cyclase; GTP, guanosine triphosphate; LPS, lipopolysaccharide; NADP, nicotinamide-adenine dinucleotide phosphate, reduced; NO, nitric oxide.

involve stimulation of these inhibitory G proteins (G_i) with subsequent inhibition of adenylyl cyclase activity.

Another cyclic nucleotide, cGMP, also causes smooth muscle relaxation. cGMP is synthesized from GTP by the enzyme guanylyl cyclase and is degraded to 5'-GMP by a PDE. PDE activity that can degrade both cAMP and cGMP has been demonstrated in the canine ureter, and various inhibitors can preferentially inhibit the breakdown of one or the other cyclic nucleotide (Weiss et al, 1981; Stief et al, 1995). Insulin has been shown to activate cAMP PDE activity in the ureter (Weiss and Wheeler, 1988), and 8-bromo-cGMP has been shown to cause relaxation of a number of smooth muscles (Schultz et al, 1979), including the ureter (Cho et al, 1984).

NO stimulates soluble guanylyl cyclase activity and causes smooth muscle relaxation (Dokita et al, 1991, 1994). Nitric oxide synthase (NOS) converts L-arginine to NO and L-citrulline in a reaction that requires nicotinamide adenine dinucleotide phosphate, reduced (NADPH). There are three NOS isoforms. Neuronal NOS (nNOS) is present in neuronal tissues and is Ca^{2+} and NADPH dependent (Bredt and Snyder, 1990). It is thought that with neuronal excitation, there is an increase in Ca^{2+} concentration within nerves that leads to the synthesis of NO from L-arginine. NO released from the nerve activates the enzyme guanylyl cyclase in the smooth muscle cell with the resultant conversion of GTP to cGMP and thus smooth muscle relaxation (Fig. 43-12). Endothelial NOS (eNOS), is Ca^{2+} and NADPH dependent (Sessa, 1994). Similar to nNOS, eNOS produces small amounts of NO for prolonged periods of time. An inducible NOS isoform (iNOS) is NADPH dependent but Ca^{2+} independent and has been identified in ureteral smooth muscle (Smith et al, 1993). iNOS produces large amounts of NO for short periods of time.

NOS-containing nerves have been demonstrated in the human ureter (Stief et al, 1993; Goessl et al, 1995; Stief et al, 1996; Iselin et al, 1998), and NOS has been demonstrated in the pig UVJ (Hernández et al, 1995; Phillips et al, 1995) and in the upper ureter and calyces of pigs and humans (Iselin et al, 1998, 1999). NOS colocalizes with vasoactive polypeptide and neuropeptide Y (NPY) in nerves supplying the human ureter (Smet et al, 1994; Iselin et al, 1997). NOS localizes to parasympathetic and sensory nerves, but not to adrenergic neurons. In primary cultures of rat ureteral cells, NO production was detected in urothelial but not in smooth muscle

cells (Mastrangelo et al, 2003). These cells contain both eNOS and iNOS.

There is evidence that the NO pathway is involved in human ureteral relaxation (Stief et al, 1996; Iselin et al, 1997). The NO donor, SIN-1, relaxes human ureteral segments, an action that is inhibited by the guanylyl cyclase inhibitor methylene blue. NO donors also inhibit agonist-induced contractions of isolated pig calyceal and rat, pig, and human intravesical ureteral segments, actions that are associated with an increase in cGMP. Furthermore, NO has been shown to be involved in nonadrenergic, noncholinergic (NANC)-induced relaxation of the pig UVJ (Hernández et al, 1995). There also is evidence that adenosine relaxes the pig intravesical ureter through a process independent of NO (Hernández et al, 1999).

Some actions of α_1 -adrenergic and muscarinic cholinergic agonists and a number of other hormones, neurotransmitters, and biologic substances are associated with an increase in intracellular Ca^{2+} and are related to changes in inositol lipid metabolism. These agonists combine with a receptor on the cell membrane, and the agonist-receptor complex, via a process that involves a G protein, activates an enzyme, phospholipase C, that leads to the hydrolysis of polyphosphatidylinositol 4,5-bisphosphate with the formation of two second messengers, IP_3 and DG (Berridge, 1984) (Fig. 43-13). IP_3 mobilizes Ca^{2+} from intracellular stores (i.e., endoplasmic reticulum or SR) with an initiation of a cascade of events through the calmodulin branch of the Ca^{2+} messenger system. In smooth muscles, IP_3 is thought to be involved in brief contractile responses or in the initial phase of sustained responses (Park and Rasmussen, 1985).

The other second messenger, DG, binds to an enzyme, PKC; translocates to the cell membrane; and, by reducing the concentration of Ca^{2+} required for PKC activation, results in an increase in this enzyme's activity. The actions of PKC involve the phosphorylation of proteins (Nishizuka, 1984). The PKC branch of the Ca^{2+}

messenger system is thought to be responsible for the sustained phase of the contractile response in smooth muscle (Park and Rasmussen, 1985) and is responsive to hormonally induced changes in intracellular Ca^{2+} . PKC has been implicated in Ca^{2+} -independent smooth muscle contractions (Yoshimura and Yamaguchi, 1997). Numerous PKC isoforms have been identified. The functional activity and specificity of function of these isoforms appear to be primarily determined by the state of phosphorylation of the isoenzyme and its subcellular localization (Dempsey et al, 2000).

DG also activates the enzyme phospholipase A, which serves as a source of arachidonic acid, the substrate for PG synthesis (Mahadevappa and Holub, 1983). Arachidonic acid, in turn, may stimulate guanylyl cyclase activity with the subsequent formation of cGMP (Berridge, 1984), and this would explain the Ca^{2+} -dependent increase in cGMP levels associated with muscarinic cholinergic and α_1 -adrenergic agonist-induced contractions in smooth muscle. The observed increases in cGMP levels follow, rather than precede, the onset of contractions induced by these agonists.

Thus, a group of second messengers are involved in the transduction of the signal that is initiated when an agonist combines with a specific receptor on the cell membrane of the smooth muscle. This process of signal transduction ultimately results in the functional response to the agonist.

MECHANICAL PROPERTIES

Mechanical characteristics of muscle are commonly assessed by defining force-length and force-velocity relations. Isometric force-length measurements depend on the number of linkages between the contractile proteins, actin and myosin, that are brought into action during contraction. Force-velocity relations depend on the rate of formation and breakdown of linkages between the contractile proteins. Interventions may affect force-velocity relations, with or without affecting force-length relations. In addition to these methods of assessing mechanical properties of the ureter, the bidimensional nature of the ureter has lent itself to studies of pressure-length-diameter relations.

Force-Length Relations

Force-length relations express the relation between the force developed by muscle when it is stimulated under isometric conditions and the resting length of the muscle at the time of stimulation. With stretching of the ureter (muscle lengthening), the resting force (i.e., the tension present when the muscle is not excited) increases at a progressive rate (Weiss et al, 1972). The force developed during isometric contraction also increases with elongation until a length is reached at which the maximal contractile force is achieved. With further lengthening, the developed force decreases (Weiss et al, 1972; Thulesius et al, 1989). The ureter at this length is overstretched, or beyond the peak of its force-length curve. Ureteral resting tension is high at the length at which maximal contractile force is developed.

Because the ureter is a viscoelastic structure (Weiss et al, 1972), the resting or contractile force developed at any given length depends on the direction in which the change in length is occurring and on the rate of length change (Weiss et al, 1972; Vereecken et al, 1973). This is referred to as *hysteresis*; for the ureter, at any given length, the resting force is less and the contractile force is greater when the ureter is allowed to shorten than when the ureter is being stretched (Fig. 43-14).

When the ureter is stretched, the resting force increases. If the length is kept constant at its new longer length after a stretch, changes occur that result in a decrease in the resting force, or stress relaxation (Fig. 43-15) (Weiss et al, 1972). Within certain limits, when the ureter is stretched to a length beyond the peak of the force-length curve—that is, when the ureter is stretched to a length at which the contractile force declines in the face of increasing muscle length—the degree of stress relaxation may be such that, within a period of time, the developed force no longer declines,

Figure 43-13. Schematic representation of the role of inositol lipid metabolism in smooth muscle function. The agonist combines with the receptor on the outer side of the cell membrane. The receptor-agonist complex in turn activates the enzyme phospholipase C (PLC), which leads to the hydrolysis of polyphosphatidylinositol 4,5-bisphosphate (PIP_2), with the formation of two second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DG). The activation of PLC involves a G protein. IP_3 mobilizes calcium from intracellular stores (i.e., endoplasmic reticulum [ER]), and this leads to a functional response. DG binds to an enzyme, protein kinase C (PKC), which results in phosphorylation of proteins and a subsequent functional response. AA, arachidonic acid.

Figure 43-14. Hysteresis. Resting and contractile (active) force of cat ureter during muscle lengthening and shortening. Force is on the ordinate; change in length (ΔL) is on the abscissa. Solid symbols and solid lines show data obtained during muscle lengthening. Open symbols and dashed lines show data obtained during muscle shortening. Circles show resting force, and triangles show active or contractile force. Length and the direction of length change influence resting and contractile force. (From Weiss RM, Bassett AL, Hoffman BF. Dynamic length-tension curves of cat ureter. *Am J Physiol* 1972;222:388.)

even though the increased length is kept constant (Weiss et al, 1972). Stress relaxation can thus be considered a compensatory mechanism of a viscoelastic structure to stretch.

Force-Velocity Relations

Force-velocity curves depict the relation between the load and the velocity of shortening. A typical force-velocity curve, as predicted by Hill's equation for muscle shortening, has a hyperbolic configuration (Fig. 43-16) (Hill, 1938). From the force-velocity curve, one can extrapolate the maximal velocity of shortening (V_{max}), which represents the velocity of shortening at zero load (i.e., at isotonic conditions). V_{max} is determined by the level at which the force-velocity curve crosses the ordinate. V_{max} values in the ureter are in the range of 0.5 to 0.7 lengths per second (Biancani et al, 1984). The force-velocity curve intersects the abscissa at zero shortening, that is, at isometric conditions at which the load is great. Shortening depends on the total load lifted, with the ureter shortening to a lesser extent with heavier loads. At conditions near those of zero load, that is, conditions of free shortening (isotonic conditions), the in vitro guinea pig ureter shortens by 25% to 30% of its initial length (Biancani et al, 1984).

Pressure-Length-Diameter Relations

Because ureteral muscle fibers are arranged in a longitudinal, circumferential, and spiral configuration (Tanagho, 1971), longitudinal and diametral deformation of the ureter are interrelated. Simultaneous studies of length and diameter changes in response to an intraluminal pressure load are another means of assessing the mechanical properties of a tubular structure. After application of an intraluminal pressure, the ureter increases in both length and diameter, a process known as *creep* (Biancani et al, 1973). Deformation in response to a given intraluminal pressure load is greater in vitro than in vivo; this difference is partially negated if the in vivo preparation is pretreated with reserpine to suppress adrenergic influences

Figure 43-15. Stress relaxation. The resting and contractile (active) force of cat ureter is on the ordinate, the time from the onset of stretching is on the lower abscissa, and the change in length (ΔL) is on the left upper corner abscissa. Muscle is stretched by a given amount and then held at a fixed length. Solid symbols and solid lines show data obtained during muscle lengthening; open symbols and dashed lines show data obtained after stretching has ceased (arrow) and muscle is maintained at a constant length. Resting force decreases when muscle is held at a constant length after a stretch (stress relaxation). Contractile (active) force increases during this period of time. (From Weiss RM, Bassett AL, Hoffman BF. Dynamic length-tension curves of cat ureter. *Am J Physiol* 1972;222:388.)

(Fig. 43-17). Such data provide support for a role of the adrenergic nervous system in the control of ureteral function.

ROLE OF THE NERVOUS SYSTEM IN URETERAL FUNCTION

Some smooth muscles have a specific innervation of each smooth muscle fiber, whereas other, syncytial-type smooth muscles lack discrete neuromuscular junctions and depend on a diffuse release of transmitter from a bundle of nerves with a subsequent spread of excitation from one muscle cell to another. The ureter is a syncytial type of smooth muscle without discrete neuromuscular junctions (Burnstock, 1970).

Because peristalsis may persist after transplantation (O'Connor and Dawson-Edwards, 1959) or denervation (Wharton, 1932), because spontaneous activity may occur in isolated in vitro ureteral segments (Finberg and Peart, 1970), and because normal antegrade peristalsis continues after reversal of a segment of ureter in situ (Melick et al, 1961), it is apparent that ureteral peristalsis can occur without innervation. However, analysis of the data in the literature clearly indicates that the nervous system plays at least a modulating role in ureteral peristalsis. Morita and colleagues (1987b) have provided evidence that the autonomic nervous system may affect urine transport through the ureter by affecting both peristaltic frequency and bolus volume. Catecholamine fluorescence and acetylcholine (ACh) release studies indicate that the human ureter is supplied by sympathetic (noradrenaline-containing) and parasympathetic (ACh-containing) neurons (Duarte-Escalante et al, 1969; Del Tacca, 1978).

Figure 43-16. Force-velocity relation of guinea pig ureter. Specimens were stretched by three different preloads (0.05, 0.1, and 0.2 g). The velocity of shortening on the ordinate is plotted as a function of the total load lifted on the abscissa. V_{\max} is obtained by extrapolating the experimental curves to intersect the ordinate. Isometric force is given by data points where velocity equals zero. (From Biancani P, Onyski JH, Zabinski MP, et al. Force-velocity relationships of the pig ureter. *J Urol* 1984;131:988. Copyright Williams & Wilkins, 1984.)

Figure 43-17. Pressure-diameter relations. An intraluminal pressure (p) load of 40 g/cm² is applied to rabbit ureters, and the change in diameter (D/D_0) is measured as a function of time. Blue squares show data obtained from in vitro ureters. Purple circles show data obtained in vivo. Pink circles show data obtained in vivo from animals previously treated with reserpine. D, diameter during deformation; D_0 , initial diameter.

Parasympathetic Nervous System

Although the role of the parasympathetic nervous system in the control of ureteral peristalsis has not been well defined, muscarinic cholinergic receptors have been demonstrated in the ureter of a number of species including the human (Latifpour et al, 1989, 1990; Hernández et al, 1993; Sakamoto et al, 2006). There are five cloned muscarinic subtypes, M_1 to M_5 . The excitatory muscarinic receptors, M_1 , M_3 , and M_5 , work through an excitatory G protein, G_q , and increase intracellular calcium by generating IP_3 and DG. The inhibitory muscarinic receptors, M_2 and M_4 , work through an inhibitory G protein, G_i , with inhibition of adenyl cyclase (Wu et al, 2000; van Koppen and Kaiser, 2003). Carbachol-induced contractile responses are primarily mediated via the M_3 receptor subtype (Tomiya et al, 2003b). It has been suggested that M_2 receptor activation may inhibit smooth muscle relaxation that results from activation of adenyl cyclase (Hegde et al, 1997). There is a higher density of M_2 than M_3 muscarinic receptors in the human ureter (Sakamoto et al, 2006).

Acetylcholinesterase-positive nerve fibers have been demonstrated in the equine ureter (Prieto et al, 1994). The cholinergic innervation is especially rich in the distal and intravesical ureter (Hernández et al, 1993). Furthermore, ACh has been shown to be released from isolated guinea pig, rabbit, and human ureters in response to EFS (Del Tacca, 1978), and this release is inhibited by the neural poison tetrodotoxin. These data suggest but do not prove that the parasympathetic nervous system has at least a modulatory role in the control of ureteral activity.

The prototypic cholinergic agonist is ACh, which serves as the neurotransmitter at (1) neuromuscular junctions of somatic motor nerves (nicotinic sites); (2) preganglionic parasympathetic and sympathetic neuroeffector junctions (nicotinic sites); and (3) postganglionic parasympathetic neuroeffector sites (muscarinic sites). ACh synthesis involves

where CoA is coenzyme A. The ACh is stored in vesicles within the synaptic terminal; its release depends on the influx of Ca^{2+} into the terminal, which presumably causes vesicle fusion with the presynaptic terminal membrane, thereby expelling ACh into the synaptic cleft. ACh subsequently is hydrolyzed by acetylcholinesterase. The muscarinic effects of cholinergic agonists can be blocked by atropine. The effects of nicotinic agonists can be blocked by nondepolarizing ganglionic blocking agents or by high concentrations of the nicotinic agonist itself, which may cause ganglionic blockade by desensitization of receptor sites after an initial period of ganglionic stimulation.

Cholinergic Agonists

Cholinergic agonists, including ACh, methacholine (Mecholyl), carbamylcholine (carbachol), and bethanechol (Urecholine), in general have been observed to have an excitatory effect on ureteral and renal pelvic function—that is, they increase the frequency and force of contractions (Verecken, 1973; Longrigg, 1974; Rose and Gillenwater, 1974; Morita et al, 1986, 1987b; Maggi and Giuliani, 1992; Hernández et al, 1993; Prieto et al, 1994). The excitatory effect of carbachol on isolated canine ureter is mediated by the excitatory M_3 -receptor subtype, and carbachol-induced inhibition of KCl-induced contractions of longitudinal canine ureteral preparations is mediated primarily via the inhibitory M_4 -receptor subtype (Tomiya et al, 2003b). ACh also has been shown to increase the duration of the guinea pig and rat ureteral action potential (Prosser et al, 1955; Ichikawa and Ikeda, 1960) and the number of oscillations on the plateau of the guinea pig ureteral action potential (Ichikawa and Ikeda, 1960).

Nicotinic agonists, such as nicotine, tetramethylammonium, and dimethylphenylpiperazine, cause an initial stimulation of nicotinic receptors followed by desensitization of the receptor sites; the receptors then become unresponsive to nicotinic agonists and also

to endogenous ACh, with a resultant transmission blockade. Nicotine, as would be expected, has been shown to have excitatory (Boyarsky et al, 1968), biphasic (Satani, 1919; Labay and Boyarsky, 1967), or inhibitory (Prosser et al, 1955; Vereecken, 1973) actions on the ureter.

Anticholinesterases

Anticholinesterases prevent the hydrolysis of ACh by cholinesterases and thus increase the duration and intensity of ACh action at both muscarinic and nicotinic receptor sites. With prolonged administration in high doses, they can result in desensitization blockade at nicotinic sites. The effects of **anticholinesterases**, such as **physostigmine** and **neostigmine**, parallel the excitatory effects of ACh and other parasympathomimetics on the ureter (Satani, 1919; Vereecken, 1973).

Parasympathetic Blocking Agents

Atropine is a competitive antagonist of the muscarinic effects of ACh. The inhibitory effects of atropine may be preceded by a transitory stimulatory effect on muscarinic receptors. Although atropine has been shown to inhibit the excitatory effects of parasympathomimetic agents (Vereecken, 1973; Longrigg, 1974) and physostigmine (Macht, 1916a) on a variety of ureteral and calyceal preparations, the majority of studies have shown that atropine itself has little direct effect on ureteral activity in a number of species (Gibbs, 1929; Gould et al, 1955; Butcher et al, 1957; Washizu, 1967; Vereecken, 1973; Reid et al, 1976), including humans (Kiil, 1957). Even when atropine has been observed to inhibit ureteral activity, its effects are frequently minimal and inconsistent (Ross et al, 1967), thus providing little rationale for its use in the treatment of ureteral colic.

Reports of the direct effects on ureteral activity of two other parasympathetic blocking agents, methantheline (Banthine) and propantheline (Pro-Banthine), also have been inconsistent (Draper and Zornigotti, 1954; Kiil, 1957; Reid et al, 1976).

Sympathetic Nervous System

The sympathetic nervous system appears to modulate ureteral activity as evidenced by the demonstration of adrenergic receptors in the ureter (Latifpour et al, 1989, 1990; Morita et al, 1994), the identification of catecholaminergic neurons in the ureter as determined by labeling tyrosine hydroxylase as a marker (Edyvane et al, 1994), and the demonstration that catecholamines are released from the ureter (Weiss et al, 1978) and renal calyx (Longrigg, 1975) in response to EFS.

The ureter contains excitatory α -adrenergic and inhibitory β -adrenergic receptors (McLeod et al, 1973; Rose and Gillenwater, 1974; Weiss et al, 1978) that have been demonstrated with receptor-binding techniques (Latifpour et al, 1989, 1990). In the human ureter, renal pelvis, and calyces, α_{1D} and α_{1A} adrenoceptor subtypes are more prevalent than the α_{1B} adrenoceptor subtype (Sigala et al, 2005; Itoh et al, 2007; Karabacak et al, 2013). The highest density of α_1 adrenoceptors is found in the distal ureter, with the relative density being α_{1D} higher than α_{1A} , which is higher than α_{1B} . This is in accord with the finding that phenylephrine, an α -adrenergic agonist, induces a greater contractile force in isolated human ureteral segments obtained from the distal than the proximal ureter (Sasaki et al, 2011). The expression of α_1 adrenoceptors is species dependent, with a higher density of α_{1A} adrenoceptors in the mouse ureter and a higher density of α_{1D} adrenoceptors in the dog and hamster ureter (Tomiya et al, 2007; Kobayashi et al, 2009a, 2009b). The α_{1A} adrenoceptor subtype is the primary receptor subtype that participates in the contraction of the mouse, hamster, and human ureter (Tomiya et al, 2007; Sasaki et al, 2008; Kobayashi et al, 2009c; Sasaki et al, 2011). It appears that α_{1A} adrenoceptors are more involved in the maintenance of baseline ureteral tonus than in the potentiation of ureteral peristaltic activity (Morita et al, 1987a; Tomiya et al, 2002).

Norepinephrine, primarily an α -adrenergic agonist (although it also can stimulate β -adrenergic receptors), increases the force of electrically induced ureteral contractions (Weiss et al, 1978). When administered in the presence of **phentolamine** (Regitine), an α -adrenergic blocking agent, norepinephrine decreases the force of ureteral contractions (Weiss et al, 1978). A similar reversal of action occurs in the in vivo ureter (McLeod et al, 1973) and can be explained by norepinephrine's primary action on inhibitory β -adrenergic receptors when the excitatory α -adrenergic receptors are blocked. Propranolol (Inderal), a β -adrenergic antagonist, potentiates the increase in contractile force induced by norepinephrine (Weiss et al, 1978). This can be explained by norepinephrine's acting more exclusively on excitatory α -adrenergic receptors when the inhibitory β -adrenergic receptors are blocked. Furthermore, **isoproterenol**, a β -adrenergic agonist, depresses contractility (Weiss et al, 1978). These data provide evidence for excitatory α -adrenergic and inhibitory β -adrenergic receptors in the ureter and are in accord with the observations of McLeod and associates (1973) and Rose and Gillenwater (1974) on in vivo ureters.

Further support for the presence of excitatory α -adrenergic and inhibitory β -adrenergic receptors in the ureter includes the demonstration of adenyl cyclase activity in the ureter (Weiss et al, 1977; Wheeler et al, 1986) and the finding that the ureters of rabbits depleted of catecholamines by the administration of reserpine undergo greater degrees of deformation when a given intraluminal pressure is applied than would result from the application of the same pressure load to the ureters of normal, non-reserpine-treated animals (see Fig. 43-17) (Weiss et al, 1974). Finally, electric stimulation with high-intensity, high-frequency, short-duration stimuli has been shown to release neurotransmitter, presumably from intrinsic neural tissue within the wall of the ureter (Weiss et al, 1978) and renal calyx (Longrigg, 1975).

Adrenergic Agonists

Norepinephrine, the chemical mediator responsible for adrenergic transmission, is synthesized in the neuron from tyrosine. After its release from the nerve terminal, some of the norepinephrine combines with receptors in the effector organ, leading to a physiologic response. The greatest percentage of the norepinephrine is actively taken up (reuptake or neuronal uptake) into the neuron. Neuronal reuptake regulates the duration that norepinephrine is in contact with the innervated tissue and thus regulates the magnitude and duration of the catecholamine-induced response. Agents such as cocaine and imipramine (Tofranil) that inhibit neuronal uptake potentiate the physiologic response to norepinephrine. The enzymes monoamine oxidase and catechol-O-methyltransferase provide degradative pathways for norepinephrine.

According to the general consensus, agents that primarily activate α -adrenergic receptors, such as norepinephrine and phenylephrine, tend to stimulate ureteral and renal pelvic activity (McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Rose and Gillenwater, 1974; Hernández et al, 1992; Rivera et al, 1992; Danuser et al, 2001), and agents that primarily activate β -adrenergic receptors, such as isoproterenol and orciprenaline, tend to inhibit ureteral and renal pelvic activity (Finberg and Peart, 1970; Ancill et al, 1972; McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978; Hernández et al, 1992; Rivera et al, 1992; Danuser et al, 2001). The β -adrenergic subtypes involved in ureteral relaxation are species specific; β_1 adrenoceptors in rat, β_2 adrenoceptors in rabbit, mainly β_3 adrenoceptors in dog, and β_2 and β_3 adrenoceptors in pig and human (Tomiya et al, 1998; Park et al, 2000; Tomiya et al, 2003a; Wanajo et al, 2004). All three β -adrenergic receptor subtypes are expressed in the human ureter (Park et al, 2000; Matsumoto et al, 2013). Immunohistochemical studies show that the β -adrenergic receptors are expressed in both the smooth muscle and the urothelium of the human ureter (Matsumoto et al, 2013). A relatively specific β_3 -adrenoceptor agonist, TRK-380, relaxes in vitro human ureteral segments, and it has been suggested that the β_3 agonist mirabegron may do the same (Matsumoto et al,

2013). A synthesized β_2/β_3 -adrenoceptor agonist, KUL-7211, was a more potent relaxant of isolated dog ureteral segments than the α -adrenergic antagonists tamsulosin and prazosin, the calcium channel blocker verapamil, and the PDE inhibitor papaverine (Wanajo et al, 2005). KUL-7211 also is a potent relaxant of the pig ureter (Wanajo et al, 2011). Intraluminal isoproterenol has been shown to lower renal pelvic pressures during ureteroscopy, with the presumption that this would decrease intrarenal backflow, which has potential harmful effects (Jung et al, 2008; Jakobsen, 2013). In rabbit renal pelvis, β_2 -adrenergic agonists inhibit contractile activity of the distal renal pelvis, and β_1 -adrenergic agonists potentiate contractile activity of the proximal renal pelvis (Kondo et al, 1989). Tyramine, whose adrenergic agonist effects are primarily the result of the release of norepinephrine from adrenergic terminals, also has a stimulatory effect on the upper urinary tract (Boyarsky and Labay, 1969; Finberg and Peart, 1970; Longrigg, 1974). The reported stimulatory effects of cocaine on ureteral activity (Boyarsky and Labay, 1969) may be explained by blockage of norepinephrine reuptake into adrenergic nerve endings, with a resultant increase in the magnitude and duration of the effect of norepinephrine.

Adrenergic Antagonists

The α -adrenergic antagonists phentolamine and phenoxybenzamine (Dibenzylamine) have been shown to inhibit the stimulatory effects of norepinephrine and other α -adrenergic agonists in a variety of preparations (Finberg and Peart, 1970; Gosling and Waas, 1971; McLeod et al, 1973; Vereecken, 1973; Hannappel and Golenhofen, 1974; Longrigg, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978; Hernández et al, 1992). The α -adrenergic antagonist doxazosin has been shown to slightly reduce spontaneous contractility of in vitro pig ureter and to inhibit the contractile effects of epinephrine and phenylephrine (Nakada et al, 2007), and tamsulosin inhibited the contractility of human ureters in vitro (Rajpathy et al, 2008) and in vivo (Davenport et al, 2007). Silodosin, a selective α_{1A} receptor antagonist, was more effective in inhibiting EFS-induced contractions of human and rat isolated ureters than tamsulosin, a selective α_{1AD} receptor antagonist, or prazosin, a non-selective α -adrenergic receptor antagonist (Villa et al, 2013). The β -adrenergic antagonist propranolol has been shown to block or attenuate the inhibitory effects of β -adrenergic agonists, such as isoproterenol, in a variety of preparations (McLeod et al, 1973; Vereecken, 1973; Longrigg, 1974; Rose and Gillenwater, 1974; Weiss et al, 1978).

Sensory Innervation and Peptidergic Agents in the Control of Ureteral Function

Sensory nerves can play both a sensory afferent and motor efferent role in a given tissue. Tachykinins and calcitonin gene-related peptide (CGRP) are neurotransmitters released from peripheral endings of sensory nerves (Maggi, 1995). Tachykinins stimulate and CGRP inhibits electrical and contractile activity. Capsaicin-sensitive sensory nerves are located in the ureter (Maggi et al, 1986; Maggi and Meli, 1988; Dray et al, 1989; Ammons, 1992) and contain the tachykinins substance P, neurokinin A, and neuropeptide K (Hua et al, 1985; Sann et al, 1992), as well as CGRP (Gibbins et al, 1985; Sann et al, 1992; Tamaki et al, 1992). Immunoreactivity for tachykinins and CGRP is less in the human than in the guinea pig ureter (Su et al, 1986; Hua et al, 1987; Edyvane et al, 1992, 1994). Capsaicin in low doses inhibits ureteral activity, presumably because of the release of CGRP, but in high doses it increases ureteral activity, presumably because of release of the tachykinins neurokinin A, neuropeptide K, and substance P (Hua and Lundberg, 1986). Capsaicin administration to neonatal rats causes degeneration of CGRP-containing sensory nerves in the ureter, which is accompanied by an increase in sympathetic (noradrenergic) innervation (Sann et al, 1995). Because nerve growth factor (NGF) is responsible for both increased sensory and noradrenergic innervation, capsaicin-induced

degeneration of sensory nerves decreases NGF uptake into sensory neurons with a resultant increase in the amount of NGF available for stimulating sympathetic innervation (Schicho et al, 1998). The excitatory effects of the tachykinins are more prominent in the renal pelvis than in the ureter, and the inhibitory effects of CGRP are more prominent in the ureter than in the renal pelvis (Maggi et al, 1992b). The excitatory effects of tachykinins involve excitation of NK-2 receptors in the human, pig, and guinea pig ureter; pig intravesical ureter; and guinea pig renal pelvis (Patacchini et al, 1998; Jerde et al, 1999; Bustamante et al, 2001; Nakada et al, 2001). The inhibitory actions of the neurotransmitter CGRP appear to involve multiple mechanisms (Maggi and Giuliani, 1991; Maggi et al, 1994c). By opening ATP-sensitive K^+ channels, CGRP causes membrane hyperpolarization with a resultant blocking of voltage-sensitive Ca^{2+} channels that are involved in generation of the ureteral action potential and ureteral contraction (Maggi et al, 1994b; Santicoli and Maggi, 1994; Meini et al, 1995). CGRP-induced ureteral relaxation may also result from stimulation of adenylyl cyclase activity with a resultant increase in cAMP (Santicoli et al, 1995b). The action of CGRP on the ureter may be regulated by an endopeptidase that degrades the CGRP released from the sensory nerves (Maggi and Giuliani, 1994).

Histochemical studies show that the tachykinins and CGRP colocalize in the same nerves in the ureter (Hua et al, 1987). Peptidergic neurons containing NPY and vasoactive intestinal polypeptide (VIP) also are present in the ureter (Allen et al, 1990; Edyvane et al, 1992; Prieto et al, 1997). VIP and pituitary adenylyl cyclase-activating polypeptide (PACAP) have been shown to relax pig intravesical ureteral segments through a cAMP-dependent mechanism (Hernández et al, 2004). Edyvane and associates (1994) have provided evidence for at least four, and possibly six, different immunohistochemical populations of nerve fibers in the human ureter. The predominant types include noradrenergic nerves containing NPY, neurons containing NPY and vasoactive polypeptide, neurons containing substance P and CGRP, and neurons containing CGRP. NPY potentiates the excitatory effects of norepinephrine on the ureter (Prieto et al, 1997). Rare coexistences also were observed between CGRP and vasoactive polypeptide, CGRP and NPY, and CGRP and tyrosine hydroxylase, a marker of noradrenergic neurons. These investigators demonstrated regional differences in the innervation of the ureter, with a more extensive innervation noted in the lower than in the upper ureter.

Renal pelvic sensory nerves contain both substance P and CGRP. Increases in renal pelvic pressure result in the release of substance P and a subsequent increase in afferent renal nerve activity. CGRP potentiates the afferent renal nerve activity responses to substance P by retarding the metabolism of substance P, thus resulting in increased amounts of substance P available for potentiating afferent renal nerve activity (Contijo et al, 1999). PGs also contribute to sensory receptor activation (Kopp et al, 2000).

NANC excitatory neurotransmission is functional in the pig intravesical ureter (Bustamante et al, 2000, 2001). In the presence of agents that block adrenergic neurotransmission, muscarinic cholinergic receptors, NO synthase activity, PG synthesis, and A_1/A_2 adenosine receptors, EFS (5 Hz) induced contractions that were potentiated by the tachykinins substance P and NKA and that were inhibited by a sensory neurotoxin, capsaicin, and by an NK₂ receptor antagonist, GR94800. The EFS-induced contractions were abolished by tetrodotoxin, providing evidence that the contractions were neurogenic in origin. It has been suggested that tachykinins, especially NKA, released from capsaicin-sensitive afferent nerves and activating NK₂ receptors are involved in NANC excitatory neurotransmission.

Purinergic Nervous System

Burnstock and associates (1972) postulated that ATP could act as an excitatory transmitter in the bladder. It was subsequently shown that ATP is released along with ACh in response to nerve stimulation (Kasakov and Burnstock, 1983) and that the excitatory response

in the bladder is mediated through P2X receptors (Theobald, 1995). ATP activation of P2X purinoceptors promotes influx of extracellular Ca^{2+} into the muscle cells with resultant contraction. Although there is no evidence that ATP mediates contractions in the ureter, there is evidence to suggest that ATP is involved in nociceptive processes. P2X receptors are present in the ureter (Lee et al, 2000). ATP is released from the urothelium of human and guinea pig ureter, in response to ureteral distention (Knight et al, 2002; Calvert et al, 2008), and stimulates sensory nerves that contain purinergic receptors (Rong and Burnstock, 2004; Calvert et al, 2008).

Two classes of mechanosensitive afferent fibers have been identified in the guinea pig ureter (Cervero and Sann, 1989). It would appear that one group of fibers consists of tension receptors that respond to normal ureteral peristalsis, whereas the others are involved in the signaling of noxious events such as kidney stones and increased intraluminal pressures. Both groups are chemosensitive, being excited by K^+ , bradykinin, and capsaicin (Sann, 1998). Because both ureteral distention and exogenous ATP increase afferent nerve discharge (Rong and Burnstock, 2004), ATP may be involved in signaling visceral pain with ureteral dilatation—that is, renal colic (Burnstock, 2006, 2009). It has been proposed that ureteral distention causes release of ATP from the urothelium, which in turn activates purinoceptors on suburothelial nociceptive sensory nerves. Consistent with this postulation, ATP has been shown to be released with distention of isolated human ureteral segments; this was accompanied by staining of P2X₃ and capsaicin receptors (Calvert et al, 2008).

URINE TRANSPORT

Physiology of the Ureteropelvic Junction

At normal urine flows, the frequency of calyceal and renal pelvic contractions is greater than that in the upper ureter, and there is a relative block of electrical activity at the UPJ (Morita et al, 1981). At these flows, the renal pelvis fills; as renal pelvic pressure rises, urine is extruded into the upper ureter, which is initially in a collapsed state (Griffiths and Notschaele, 1983). Ureteral contractile pressures that move the bolus of urine are higher than renal pelvic pressures, and a closed UPJ may be protective of the kidney in dissipating backpressure from the ureter. As the flow rate increases, the block at the UPJ ceases and a 1:1 correspondence between pacemaker and ureteral contractions develops (Constantinou and Hrynczuk, 1976; Constantinou and Yamaguchi, 1981).

With UPJ obstruction, there may be areas of narrowing or valve-like processes (Maizels and Stephens, 1980) or mucosal folds (Takeyama and Sakai, 2007). In other instances, there is no gross narrowing at the UPJ, and abnormal propagation of the peristaltic impulse is a causative factor in the obstruction. In these instances, there appears to be a functional obstruction at the UPJ, because a large-caliber catheter can be passed readily through the UPJ even though urine transport is inadequate. Murnaghan (1958) related the functional abnormality to an alteration in the configuration of the muscle bundles at the UPJ, and Foote and associates (1970) observed a decrease in musculature at the UPJ. Hanna (1978), in an electron microscopic study of severe UPJ obstructions, noted abnormalities in the musculature of the renal pelvis and disruption of intercellular relations at the UPJ itself. Increased accumulation of collagen has been described in the region of the UPJ with obstruction (Murakumo et al, 1997), and it has been suggested that differences in types I and III collagen in the region of the obstructed UPJ may be age dependent (Yoon et al, 1998). Increases in smooth muscle myosin heavy chain isoforms also have been described in congenital UPJ obstruction (Hosgor et al, 2005). Studies also have shown a decrease in nerves and in NGF messenger RNA (mRNA) expression in UPJ obstruction specimens compared with controls (Wang et al, 1995; Murakumo et al, 1997). An increase in apoptosis of smooth muscle cells in the region of congenital UPJ obstruction has been reported to accompany a

decrease in smooth muscle and nerve terminals and an increase in collagen and elastin (Kajbafzadeh et al, 2006). c-KIT-positive ICC-like cells, which appear to aid in the propagation of electrical impulses from pacemaker cells to typical ureteral smooth muscle cells, have been reported to be both decreased (Solari et al, 2003; Yang et al, 2009) and increased (Koleda et al, 2012) at the obstructed UPJ. Defective contractility of UPJ segments obtained at the time of pyeloplasty has been described (Pontinca et al, 2006). A vessel or adhesive band crossing the UPJ may potentiate the degree of dilatation in any of the forms of UPJ obstruction.

The differences in the reported findings suggest a histopathologic spectrum in the group of cases referred to as *UPJ obstructions*. It appears possible that, at least in some instances, disruption of cell-to-cell propagation of peristaltic activity results in impairment of urine transport across the UPJ.

One must consider input and output when predicting whether or not dilatation will occur; the effects of diuresis and obstruction appear to be complementary and additive with respect to the development of renal pelvic and calyceal dilatation. Some UPJs can handle urine flow regardless of the magnitude of diuresis, others cause dilatation at even the lowest flows, and still others can handle low flows but cause massive dilatation at high flows (Fig. 43-18).

Propulsion of Urinary Bolus

The theoretic aspects of the mechanics of urine transport within the ureter have been described in detail by Griffiths and Notschaele (1983); these are depicted in Figure 43-19.

At normal flow rates, as the renal pelvis fills, a rise in renal pelvic pressure occurs and urine is extruded into the upper ureter, which initially is in a collapsed state. The contraction wave originates in the most proximal portion of the ureter and moves the urine in front of it in a distal direction. The urine that had previously entered the ureter is formed into a bolus. To propel the bolus of urine efficiently, the contraction wave must completely coapt the ureteral walls (Woodburne and Lapides, 1972; Griffiths and Notschaele, 1983), and the pressure generated by this contraction wave provides the primary component of what is recorded by intraluminal pressure measurements. The bolus that is pushed in front of the contraction wave lies almost entirely in a passive, noncontracting part of the ureter (Fung, 1971; Weinberg, 1974).

Baseline, or resting, ureteral pressure is approximately 0 to 5 cm H₂O, and superimposed ureteral contractions ranging from 20 to 80 cm H₂O occur two to six times per minute (Kiil, 1957; Ross et al, 1972). The urine traverses the UPJ to enter the bladder; when functioning properly, the UPJ ensures one-way transport of urine. The bolus is forced into the bladder by the advancing contraction wave, which then dissipates at the UPJ.

As with any tubular structure, the ureter can transport a set maximal amount of fluid per unit time. Under normal flows, in which bolus formation occurs, the amount of urine transported per unit time is significantly less than the maximal transport capacity of the ureter. At extremely high flows, as are used in perfusion studies (Whitaker, 1973), the ureteral walls do not coapt, and a continuous column of fluid, rather than a series of boluses, is transported.

When transport becomes inadequate, stasis of urine occurs with resultant ureteral dilatation. Inadequate transport can result either from too much fluid entering the ureter per unit time or from too little fluid exiting the ureter per unit time. Both input and output must be considered in predicting whether or not ureteral dilatation will occur. For example, a minor degree of obstruction to outflow will cause more dilatation at high flow rates than at low flow rates. Even a normal unobstructed ureter will impede urine transport if the rate of flow is great enough.

Changes in ureteral dimensions that occur in pathologic states may, per se, result in inefficient urine transport, even if the contractile force of the individual fibers is unchanged. The Laplace

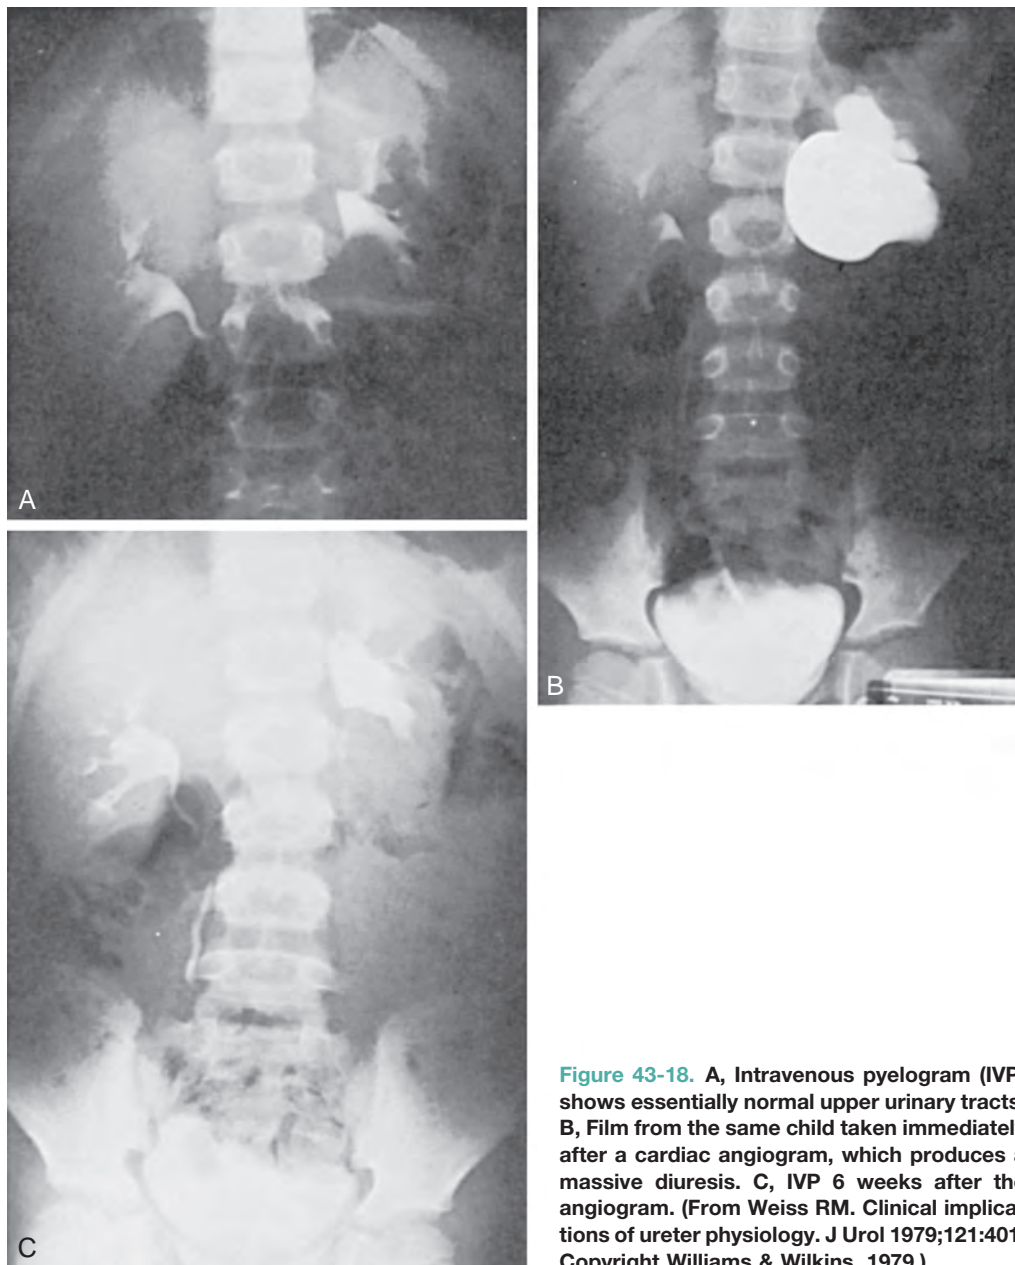

Figure 43-18. A, Intravenous pyelogram (IVP) shows essentially normal upper urinary tracts. B, Film from the same child taken immediately after a cardiac angiogram, which produces a massive diuresis. C, IVP 6 weeks after the angiogram. (From Weiss RM. Clinical implications of ureter physiology. *J Urol* 1979;121:401. Copyright Williams & Wilkins, 1979.)

equation expresses the relation between the variables that affect intraluminal pressure:

$$\text{Pressure} = \frac{\text{tension} \times \text{wall thickness}}{\text{radius}}$$

An increase in ureteral diameter in itself can decrease intraluminal pressure and result in inefficient urine transport. Such dimensional changes may, at least theoretically, be deleterious (Griffiths, 1983). Another factor may be the histologic composition of the dilated ureter, as evidenced by the description of different amounts of type I and type III collagen in primary obstructed and refluxing megaureters (Lee et al, 1998).

Effect of Diuresis on Ureteral Function

With increasing urine flow rates, the initial response of the ureter is to increase peristaltic frequency. After the maximal frequency is achieved, further increases in urine transport occur by means

of increases in bolus volume (Morales et al, 1952; Constantinou et al, 1974). At relatively low flow rates, small increases in flow result in large increases in peristaltic frequency. At higher flow rates, relatively large increases in flow result in only small increases in peristaltic frequency. As the flow rate continues to increase, several of the boluses coalesce, and finally the ureter becomes filled with a column of fluid and dilates. At these high flow rates, urine transport is through an open tube.

Effects of Bladder Filling and Neurogenic Vesical Dysfunction on Ureteral Function

Ureteral dilatation can result either from an increase in fluid input or from a decrease in fluid output from the ureter. The relation between ureteral intraluminal pressure and intravesical pressure is important in determining the efficacy of urine passage across the UVJ into the bladder. In the case of the normal ureter under normal physiologic rates of flow, ureteral contractile pressure exceeds intravesical pressure, resulting in passage of urine into the bladder. In

Figure 43-19. Schematic representation of a single bolus in the ureter moving away from the renal pelvis and toward the bladder. Arrow C indicates the direction of bolus transport. The corresponding distribution of pressure within the urinary tract is shown in the lower tracing. UVJ, ureterovesical junction. (From Griffiths DJ, Notschaele C. The mechanics of urine transport in the upper urinary tract. *Neurourol Urodyn* 1983;2:155.)

the dilated, poorly contracting ureter or in the normal ureter at extreme flow rates, the ureter does not coapt its walls to form boluses, and the baseline pressure in the column of urine within the ureter must exceed intravesical pressure for urine to pass into the bladder.

The pressure within the bladder during the storage phase is of paramount importance in determining the efficacy of urine transport across the UVJ. This is the pressure that the ureter needs to work against for the longest period of time. During filling of the normal bladder, sympathetic impulses and the viscoelastic properties of the bladder wall inhibit the magnitude of the intravesical pressure rise—that is, the tonus limb. With filling, the normal bladder maintains a relatively low intravesical pressure (McGuire, 1983) that facilitates the transport of urine across the UVJ and prevents ureteral dilatation. In the noncompliant fibrotic bladder and in some forms of neurogenic vesical dysfunction, the bladder is autonomous, and relatively small increases in bladder volume result in large increases in intravesical pressure with resultant impairment of ureteral emptying. The ureter initially responds to its decreased ability to empty by increasing its peristaltic frequency (Zimskind et al, 1969; Rosen et al, 1971; Fredericks et al, 1972). Ultimately, stasis occurs with the development of ureteral dilatation. The ureter has been shown to decompensate when sustained intravesical pressure approaches 40 cm H₂O (McGuire et al, 1981).

Physiology of the Ureterovesical Junction

Griffiths (1983) has analyzed the factors involved in urine transport across the UVJ. Under normal conditions and at normal flow rates, the contraction wave, which occludes the ureteral lumen, propagates distally with the urine bolus in front of it. When the bolus reaches the UVJ, the pressure within the bolus must exceed intravesical pressure for the bolus of urine to pass across the UVJ into the bladder. Under these conditions, in which the contraction wave is able to coapt the ureteral wall and move the urinary bolus distally, the pressure generated by the contraction wave exceeds the pressure within the urinary bolus. The contracted ureteral ring just proximal to the ureteral orifice at the UVJ is relevant in the antireflux

mechanism (Roshani et al, 1996). As the bolus is ejected into the bladder, the distal ureter retracts within its sheaths; this telescoping of the ureter within its sheaths aids in decreasing UVJ resistance to flow and thus facilitates urine passage into the bladder (Blok et al, 1985). The UVJ does not relax (Weiss and Biancani, 1983). Impediment of efficient bolus transfer across the UVJ into the bladder can occur when there is an obstruction at the UVJ, when intravesical pressure is excessive, or when flow rates are so high as to exceed the transport capacity of the normal UVJ. Under such conditions, in which the bolus of urine cannot pass freely into the bladder, the pressure within the bolus increases and may exceed the pressure in the contraction wave. This results in an inability of the contraction wave to completely occlude the ureter; there is retrograde flow of urine from the bolus, and only a fraction of the urinary bolus passes across the UVJ into the bladder. Griffiths (1983) has presented theoretic evidence to show that a similar situation of impaired bolus transport across the UVJ would be expected if the ureter were wide or weakly contracting, even if the UVJ were perfectly normal. The wider and more weakly contracting the ureter, the lower the UVJ resistance must be to not interfere with bolus transport. The resistance to flow at the UVJ has been variously attributed to forces in the trigone (Tanagho et al, 1968) and to detrusor pressure (Coolsaet et al, 1982).

The theoretic considerations outlined by Griffiths (1983) have direct clinical implications. If the UVJ is obstructed (i.e., has an abnormally high resistance to flow) or if the detrusor pressure is excessive, large boluses occurring at high-flow conditions would not be completely discharged into the bladder, because the contraction wave pushing the bolus would be forced open and intraureteral reflux would occur. Such obstruction at the UVJ would be detected by perfusion studies as popularized by Whitaker (1973) (i.e., the Whitaker test). On the other hand, the theory of Griffiths (1983) suggests that a similar breakdown of bolus discharge into the bladder can occur in the wide or weakly contracting ureter at high flow rates even if the UVJ is normal and that such a condition would go undetected by a Whitaker perfusion test.

There is evidence that gravity may assist urine transport and that the erect position may aid urine transport across the UVJ, especially in individuals with dilated upper tracts (Schick and Tanagho, 1973). From a practical standpoint, George and associates (1984) suggested that bed rest may be deleterious to renal function in individuals with urinary retention and wide upper urinary tracts.

PATHOLOGIC PROCESSES AFFECTING URETERAL FUNCTION

Effect of Obstruction on Ureteral Function

General

The effect of obstruction on ureteral function depends on the degree and duration of the obstruction, on the rate of urine flow, and on the presence or absence of infection. After the onset of obstruction, a backup of urine occurs within the urinary collecting system, along with an associated increase in baseline (resting) ureteral intraluminal pressure and an increase in ureteral dimensions—that is, an increase in both length and diameter (Fig. 43-20) (Rose and Gillenwater, 1973; Biancani et al, 1976). The increase in intraluminal pressure depends on the kidney's continued production of urine that cannot pass beyond the site of obstruction; the increase in ureteral dimensions results from the increased ureteral intraluminal pressure and the increased volume of urine retained within the ureter. A transient increase in the amplitude and frequency of the peristaltic contraction waves accompanies these initial dimensional and ureteral baseline (resting) pressure changes (Rose and Gillenwater, 1978; Hammad et al, 2011). There also is a decrease in the velocity of electrical impulses which correlates with decreased peristaltic activity (Hammad et al, 2011). With time, as the ureter fills with urine, the peristaltic contraction waves become smaller and are unable

Figure 43-20. Intraluminal pressure and diameter changes after obstruction of rabbit ureter. The time from the onset of obstruction is on the abscissa. The change in diameter (D/D_0) is on the upper ordinate, and the intraluminal pressure is on the lower ordinate. During the initial 3 hours of obstruction, intraluminal pressure increased to reach a maximum and was associated with an increase in diameter. Three to 6 hours after the onset of obstruction, pressure declined, although diametral deformation persisted. After 6 hours, pressure remained essentially unchanged, although the diameter continued to increase. Each data point represents the mean \pm standard error of mean (SEM). D, diameter during deformation; D_0 , initial diameter; P, intraluminal pressure. (Modified from Biancani P, Zabinski MP, Weiss RM. Time course of ureteral changes with acute and chronic obstruction. *Am J Physiol* 1976;231:393.)

to coapt the ureteral wall. Urine transport then becomes dependent on hydrostatic forces generated by the kidney (Rose and Gillenwater, 1973). Superimposed infection may result in a complete absence of contractions in the obstructed ureter and contributes to impairment of urine transport (Rose and Gillenwater, 1973).

Within a few hours after the onset of obstruction, the intraluminal baseline ureteral pressure reaches a peak and then declines to a level only slightly higher than the normal baseline pressure. This occurs at a time in which dimensional changes remain stable (Biancani et al, 1976). The decrease in ureteral pressure can be attributed to changes in intrarenal hemodynamics, such as a reduction in renal blood flow (Vaughan et al, 1971), with resultant decreases in the glomerular filtration rate and intratubular hydrostatic pressure (Gottschalk and Mylle, 1956). Fluid reabsorption into the venous and lymphatic systems and a decrease in wall tension also may play a role in the reduction in baseline ureteral pressure (Rose and Gillenwater, 1978). The persistence of dimensional changes in the face of a decrease in intraluminal pressure depends on the hysteric properties of the viscoelastic ureteral structure (Fig. 43-21) (Weiss et al, 1972; Biancani et al, 1973; Vereecken et al, 1973; Biancani et al, 1976).

Figure 43-21. Demonstration of hysteric properties of ureter show that dimensional changes depend on intraluminal pressure and on the direction of change of that pressure. At comparable pressures, deformations are greater during ureteral emptying than during ureteral filling. The blue line shows data obtained during loading; the pink line, data obtained during unloading. D, diameter during deformation; D_0 , initial diameter; P, intraluminal pressure in grams per square centimeter. (Modified from Biancani P, Zabinski MP, Weiss RM. Time course of ureteral changes with acute and chronic obstruction. *Am J Physiol* 1976;231:393.)

As the obstruction persists, there is a gradual increase in ureteral length and diameter, which reaches considerable dimensions. This occurs even though ureteral pressure remains at a relatively low and constant level. This process, observed in viscoelastic structures, is referred to as *creep* (Biancani et al, 1973). A continued, albeit small, urine production is required for the continuing increase in intraureteral volume. Such changes account for the relatively low intrapelvic pressures clinically observed in the massively dilated, chronically obstructed upper urinary tract (Backlund et al, 1965; Struthers, 1969; Vela-Navarrete, 1971; Djurhuus and Stage, 1976) and in experimentally produced obstruction (Schweitzer, 1973; Koff and Thrall, 1981a). One could postulate that with prolonged complete obstruction, the total cessation of urine output ultimately occurs. A subsequent decrease in ureteral dimensions would depend on whether urine is reabsorbed and on the mechanical properties of the ureter at that time.

To determine the effect of obstruction on the contractile properties of the ureter, a rabbit model in which the ureter is totally obstructed for 2 weeks has been used (Hausman et al, 1979; Biancani et al, 1982). After 2 weeks of obstruction, the cross-sectional muscle area increases by 250%, ureteral length by 24%, and ureteral outer diameter by 100%. In addition to undergoing muscle hypertrophy, in vitro segments from obstructed ureters develop greater contractile forces, in both longitudinal and circumferential directions, than do segments from control ureters (Fig. 43-22). With experimental obstruction at the UPI, there also is an increase in the frequency and amplitude of spontaneous mechanical contractions of the renal pelvis and an increase in the amplitude of phenylephrine and serotonin (5-hydroxytryptamine [5-HT]) induced contractions (Ekinci et al, 2004). Determination of stress (force per unit area of muscle) provides a means of determining whether the

observed increases in developed force result from an increase in contractility or from an increase in muscle mass alone. The increases in force were associated with an increase in maximal active circumferential stress but no change in maximal active longitudinal stress (Fig. 43-23). Because there is an increase in circumferential stress and no change in longitudinal stress, the sum of the stresses (total stress) or overall contractility increases after 2 weeks of obstruction. For these differences in longitudinal and circumferential stresses to occur after obstruction, rotation of muscle bundles must occur;

otherwise, longitudinal and circumferential stresses would increase equally. The rotation could result from the greater increase in diameter than in length after obstruction, from remodeling of the muscle fibers, or from both. In addition to an increase in EFS-induced ureteral contractions with obstruction, carbachol, phenylephrine, and KCl also caused a greater increase in contractions in obstructed ureters, and the Rho-kinase inhibitor, Y-27632, has a more pronounced effect in inhibiting these contractile events in obstructed ureters (Turna et al, 2007). The expression of the two Rho-kinase

isoforms, ROCK-1 and ROCK-2, is increased in the obstructed ureter (Turna et al, 2007).

Thus, the ureter dilated after 2 weeks of obstruction is not mechanically decompensated but rather undergoes changes that result in an increase in contractility. Despite both the muscle hypertrophy and the increase in contractility, it is clinically and experimentally evident that the obstructed, dilated ureter is less able than the normal ureter to generate the contractile pressures required for urine transport (Rose and Gillenwater, 1973). The decrease in the ability to generate an intraluminal pressure despite an increase in contractility results from the increase in ureteral diameter that occurs after obstruction and can be explained by the Laplace equation:

$$\text{Pressure} = \frac{\text{stress} \times \text{wall thickness}}{\text{radius}}$$

Although contractility (stress) increases after 2 weeks of obstruction, the decrease in the wall's thickness-to-radius ratio, resulting from the marked increase in intraluminal diameter and thinning of the muscle layer, accounts for the decrease in pressure. It must be realized that a longer duration of obstruction or the presence of infection may alter these relations.

Estimates of intraluminal pressures as a function of diameter (pressure-diameter curves) can be calculated from in vitro circumferential force-length data (Fig. 43-24) (Biancani et al, 1982; Weiss and Biancani, 1982) and provide insight as to how obstruction interferes with urine transport. The validity of such calculations is supported by their correspondence to actual in vivo measurements (Rose and Gillenwater, 1973; Biancani et al, 1976). The obstructed ureter at in vivo dimensions has a higher resting (baseline) pressure and a lower contractile (active) pressure than does a control ureter. In the control ureter, the total (active plus passive or resting) pressure developed at all diameters exceeds the passive pressure marked by the horizontal dotted line, and thus the generated active or contractile pressures are able to fully coapt the ureteral lumen and propel the urine bolus. In the obstructed ureter at diameters less

than 3.3 mm, the passive pressure, as marked by the horizontal dotted line, exceeds the total pressure. The contraction ring therefore is incapable of contracting below this diameter, and the pressure in the whole ureter remains approximately uniform and equal to the passive pressure. The principal effect of the contraction wave in the obstructed dilated ureter is to slightly reduce the ureteral volume and thereby slightly raise the overall resting pressure. Thus, although the obstructed ureter is able to develop greater circumferential contractile forces than the control ureter, the expected intraluminal pressure generated by the obstructed ureter would differ little from baseline (resting) pressure, and the contraction wave occurring during propagation of peristalsis would be incapable of coapting the ureteral lumen and propelling the urine bolus in an effective manner.

It should be noted that the calculated active pressure in the obstructed ureter estimates the pressure that would develop if the whole ureter were to contract simultaneously and uniformly throughout its whole length, rather than the pressure measured in a peristaltic contraction wave, which involves contraction of only a small segment of ureter at a given time. The fact that the calculated pressures in the obstructed ureter are, if anything, a slight overestimate of expected pressures only further supports the conclusion that the obstructed ureter is incapable of coapting its lumen and efficiently propelling the urine bolus. If, however, the urine were removed from the lumen of the ureter (e.g., by relieving the obstruction), the ureter obstructed for 2 weeks would be able to immediately coapt its lumen and produce pressures comparable with those of control ureters. This can be appreciated from Figure 43-24, in which the total pressure in the obstructed ureter near zero diameter can be seen to be comparable with the total pressure in the control ureter at a similar diameter. Thus, 2 weeks of obstruction results in an increase in ureteral contractility but a decrease in contractile intraluminal pressures. This decrease in the ability to generate an active intraluminal pressure and to coapt the ureteral lumen impairs urine transport in the obstructed ureter.

Obstruction of the fetal ureter also is accompanied by an increase in ureteral weight, smooth muscle mass, extracellular matrix, and the frequency and amplitude of spontaneous ureteral contractile activity (Santis et al, 2000). Obstructed and refluxing dilated ureters have an increase in type I and type III collagen and an increased ratio of collagen to smooth muscle (Gearhart et al, 1995; Lee et al, 1998). Hydrocortisone, verapamil (a calcium channel blocker), and D-penicillamine reduce collagen III production, which is increased in a variety of obstructed ureteral states and in ureteral cell cultures (Wolf et al, 1996). Obstruction also has been shown to alter the hierarchic organization of the multiple coupled pacemakers that normally coordinate peristaltic activity (Constantinou and Djurhuus, 1981; Djurhuus and Constantinou, 1982). Such disruption causes discoordination of the pelvic contractility with resultant incomplete emptying of the renal pelvis that contributes to upper urinary tract dilatation. Retrograde propagation of electrical activity or absence of electrical activity has been observed distal to an experimental obstruction (Hammad et al, 2011).

Physiologic Methodologies for Assessing Clinical Obstruction

Various radiographic methodologies, the rationale for the use of which is based on physiologic principles, are used in the evaluation and differentiation of upper urinary tract dilatation and obstruction. Description of these examinations, which include diuretic urography, diuretic magnetic resonance urography, diuretic ultrasonography, diuretic radionuclide renography, pulsed Doppler sonographic assessment of renal vascular resistance, and ultrasonographic evaluation of ureteral peristalsis, is beyond the scope of this chapter. The best methods now available for differentiating obstructive from nonobstructive dilatation depend on assessing the efficacy of urine transport. When transport becomes inadequate, urine stagnates and dilatation occurs. Dilatation depends on the compliance of the system and can result either from too much fluid entering the

Figure 43-24. Pressure-diameter relationships of control and obstructed ureters. Calculated total, active, and passive pressures are shown as a function of intraluminal diameter (D). In vivo passive pressures are indicated by horizontal dashed lines and in vivo dimensions by vertical dashed lines. (Modified from Biancani P, Hausman M, Weiss RM. Effect of obstruction on ureteral force-length relations. *Am J Physiol* 1982;243:F204.)

system per unit time or from too little fluid exiting the system per unit time. The properly functioning upper urinary tract should transport urine over the entire range of physiologically possible flow rates without undergoing marked deformational changes or increases in intraluminal pressure of a magnitude that would be deleterious to the function of the ureter, renal pelvis, or kidney.

Measurement of basal or resting intraluminal pressures does not help in differentiating obstructive from nonobstructive dilatation, because the pressures may be low even when obstruction is present (Backlund et al, 1965; Struthers, 1969; Vela-Navarrete, 1971). The values obtained vary with the state of hydration, the degree of renal function, the severity and duration of obstruction, and the compliance of the system. Perfusion studies are used in an attempt to differentiate dilated systems that are obstructed from dilated systems that are not obstructed (Backlund and Reuterskiöld, 1969a, 1969b; Reuterskiöld, 1969, 1970; Whitaker, 1973, 1978). The technique involves cannulating the dilated upper urinary tract and perfusing the system at a rate of 10 mL/min. Pressures are measured after the achievement of steady-state conditions, which occur when an equilibrium is reached between the flow into and out of the system. Fluoroscopic monitoring aids in the interpretation of the data. The basic hypothesis in perfusion studies is that if the dilated upper urinary tract can transport 10 mL/min (a fluid load greater than it would ever be expected to handle during usual physiologic states) without an inordinate increase in pressure, any degree of obstruction that is present is not clinically significant. Whitaker (1978) and Whitaker and Flower (1981) concluded from a large clinical experience that under these flow conditions, a pressure less than 15 cm H₂O correlates with a non-obstructive state, whereas pressures greater than 22 cm H₂O invariably correlate with clinically significant obstruction (Whitaker, 1978; Witherow and Whitaker, 1981). With this definition, minor degrees of obstruction could go undetected; however, the presumption is that if at high flows the hydrostatic pressure in the system is not at a level that would produce renal deterioration, then lower, more physiologic flows surely will be tolerated. The high flows are used to stress the system and thus to detect the slightest propensity to obstruction. The interpretation of data obtained by perfusion studies is schematically shown in Figure 43-25.

For relevant information to be obtained, strict adherence to detail is required in the performance of perfusion studies. Care must be taken to ensure that an equilibrium state has been reached before pressure is measured. Extrinsic factors that affect the resistance to flow, such as the needle size, length and compliance of extrinsic tubing, viscosity of the perfusion fluid, temperature, and flow rate, must be considered when quantitative data are obtained (Toguri and Fournier, 1982). Furthermore, the bladder should be continuously drained to eliminate the bladder's effect on urine transport.

When performed and interpreted properly, perfusion studies may provide clinically relevant information in select patients. The basic problem in the interpretation of data with this and other diagnostic methods is the definition of "clinically relevant obstruction"—that is, just how much resistance to flow or increase in pressure is required to produce renal functional or anatomic deterioration as a function of time, taking into account the compliance of the system (Koff and Thrall, 1981b). Also, it is theoretically possible that the wide or weakly contracting ureter at high flow rates may interfere with bolus transport even if the UVJ is normal (Griffiths, 1983). Such an obstructive process would not be detected by perfusion studies.

These theoretic considerations provide a rationale for **ureteral tapering** (Hendren, 1970). The Laplace equation provides a possible explanation for anticipated improvement in function resulting from tapering. With ureteral tapering, muscle thickness and the ability of the ureteral fibers to contract (stress) are unchanged. The decrease in radius resulting from tapering itself, according to the Laplace equation, could account for higher intraluminal pressures, which could improve urine transport. Thus, the tapered ureter may coapt its walls more readily and generate higher intraluminal pressures even though the material itself has not changed (Weiss and Biancani, 1982). Although the possibility of deleterious effects

Figure 43-25. Schematic representation of data that can be obtained with perfusion studies. A fast perfusion rate, 10 mL/min, would be used in a standard Whitaker test. A slow perfusion rate, less than 1 mL/min, would be closer to more physiologic rates of flow. (From Weiss RM. Clinical implications of ureteral physiology. *J Urol* 1979;121:401. Copyright Williams & Wilkins, 1979.)

of the wide "nonobstructed" ureter remains controversial, one should consider such effects when interpreting data obtained with the present modalities for diagnosing obstruction and when determining management.

Relation between Vesicoureteral Reflux and Ureteral Function

Factors that have been implicated in the development of vesicoureteral reflux include (1) anatomic and functional abnormalities at the UVJ, (2) inordinately high intravesical pressures, and (3) impaired ureteral function. The normal intravesical ureter is approximately 1.5 cm in length and takes an oblique course through the bladder wall. It is composed of an intramural segment surrounded by detrusor muscle and a submucosal segment that lies directly under the bladder urothelium (Tanagho et al, 1968). The relation between the length and the diameter of this intravesical segment of ureter appears to be a factor in the prevention of vesicoureteral reflux. Paquin (1959) noted that the normal ratio of intravesical tunnel length to ureteral diameter was 5:1, and Tanagho and associates (1969) noted that the ratio was 1.4:1 in children with vesicoureteral reflux. The 5:1 ratio may be an overestimation, and a more recent study reported the proportion of intravesical ureteral length to intravesical ureteral diameter to be 2.23:1 (Oswald et al, 2003b).

The ratio of intravesical ureteral length to ureteral diameter is smaller in the fetus, being 0.69:1 and 1.23:1 in 11- and 20-week-old fetuses, respectively (Oswald et al, 2003a). Reflux may occur when the intravesical tunnel is destroyed. Trigonal function also may be a factor in the prevention of vesicoureteral reflux. Tanagho and associates (1965) created vesicoureteral reflux in the cat by disruption of the trigone or by sympathectomy and, conversely, increased the pressure within the intravesical ureter by electric stimulation of the trigone or by administration of IV epinephrine. The development of vesicoureteral reflux in individuals with bladder outlet obstruction and neurogenic vesical dysfunction provides evidence that increased intravesical pressures may also be a factor in certain instances of reflux.

A significant percentage of units with vesicoureteral reflux improve spontaneously with age. In a study by Jørgensen and colleagues (1984), 35% of young pigs had vesicoureteral reflux, which disappeared with age. In the pig, significant growth and organization of smooth muscle and increase in innervation occur during the postnatal period, and this might be the anatomic correlate of maturation of the UVJ during infancy and the spontaneous functional disappearance of reflux (Pirker et al, 2007).

Although an abnormality of the UVJ is the primary causative factor in most cases of reflux, there is evidence to suggest that decreased ureteral peristaltic activity can be a contributory factor. This may explain why a normal ureter may not reflux even when reimplanted into a bladder without a submucosal tunnel (Debruyne et al, 1978) or why a defunctionalized refluxing ureter may cease to reflux when a proximal diversion is taken down (Teale et al, 1976; Weiss, 1979). The observation that vesicoureteral reflux may temporarily cease after ureteral electric stimulation (Melick et al, 1966) further supports this possibility.

Even the mildest forms of vesicoureteral reflux are associated with a decreased frequency of ureteral peristalsis (Kirkland et al, 1971; Weiss and Biancani, 1983). Although this may offer further evidence that decreased peristaltic activity is a possible causative factor in the development of reflux, an alternative interpretation is that the decreased peristaltic activity reflects changes in ureteral or renal function resulting from the reflux. Finally, the success rate of antireflux procedures is lower with poorly functioning dilated ureters, and, although this may be related to technical factors, decreased peristaltic activity may be another reason for failure.

Studies in normal and mildly refluxing systems have shown that there is a high-pressure zone in the distal ureter, with a resultant pressure gradient across the UVJ (Weiss and Biancani, 1983).

Although the cause of the UVJ gradient is not known, the weight of the fluid within the bladder compressing the intravesical ureter may be a factor. Another causative factor may be bladder or trigonal tension involving myogenic or neurohumoral mechanisms. With bladder filling, there is an increase in the amplitude of the high-pressure zone that is greater in nonrefluxing than in refluxing systems. With bladder filling, the resultant UVJ-bladder pressure gradient increases in nonrefluxing systems, whereas it decreases and may disappear in refluxing systems (Fig. 43-26) (Weiss and Biancani, 1983). This decrease in pressure gradient may correspond to the time when reflux occurs and may be related to lateralization of the ureteral orifice and shortening of the intravesical tunnel. More recent studies have shown a decrease in basal and maximum pressures at the UVJ of refluxing ureters that correlated with histologic changes (Arena et al, 2007). The histologic changes included a degree of smooth muscle deterioration and atrophy, an increase in collagen deposition, and fewer c-KIT-positive ICC-like cells at the UVJ in patients with vesicoureteral reflux (Oswald et al, 2004; Schwentner et al, 2005; Arena et al, 2007). MMP-1 production and the number of CD-68+ macrophages are increased, whereas S-100 positive myelinated nerves are decreased in the distal portion of refluxing ureters (Oswald et al, 2004; Radmayr et al, 2010). MMP-1 cleaves collagen and is frequently seen in collagen-rich regions. Some MMPs can damage nerves. CD-68+ macrophages presumably phagocytize cells undergoing apoptosis. Contraction of the longitudinal muscles at the UVJ also may function as an active antireflux mechanism (Schwentner et al, 2005).

Effect of Infection on Ureteral Function

Infection within the upper urinary tract may impair urine transport. Pyelonephritis in the monkey has been associated with decreased peristaltic activity (Roberts, 1975). Furthermore, Rose and Gillenwater (1973) have shown that infection can potentiate the deleterious effects of obstruction on ureteral function. In 1913, Primbs showed that *Escherichia coli* and staphylococcal toxins inhibited contractions of in vitro guinea pig ureteral segments (Primbs, 1913). A number of studies have confirmed that bacteria and *E. coli* endotoxin can inhibit ureteral activity (Grana et al, 1965; King and Cox, 1972), although these findings have not been universal (Struthers, 1976; Thulesius and Araj, 1987). Uropathogenic *E. coli* (UPEC) decreased phasic and high K-induced contractions of isolated human and rat ureteral segments (Floyd et al, 2010). These inhibitory changes were the result of activation of K channels

Figure 43-26. A, Ureterovesical junction pressures. Bladder pressure is approximately 0 cm H₂O with the bladder empty and is labeled "BP" with the bladder full. B, Pressure gradient across the ureterovesical junction, obtained by subtracting the bladder pressure from the ureterovesical junction pressure. (From Weiss RM, Biancani P. Characteristics of normal and refluxing ureterovesical junctions. *J Urol* 1983;129:858. Copyright Williams & Wilkins, 1983.)

with resultant inhibition of calcium entry through voltage dependent L-type calcium channels. UPEC also caused impairment of urothelial barrier function. Urothelial cells also show an increased expression of iNOS in response to bacterial invasion. Activation of iNOS leads to the formation of NO, a known smooth muscle relaxant, and this may contribute to inhibitory effects of infection on ureteral contractility (Poljakovic and Persson, 2003).

In humans, irregular peristaltic contractions with an often-decreased amplitude have been recorded with infection, and an absence of activity has been noted in the more severe cases (Ross et al, 1972). Furthermore, ureteral dilatation has been reported to result from retroperitoneal inflammatory processes secondary to appendicitis, regional enteritis, ulcerative colitis, or peritonitis (Makker et al, 1972). Infection also may reduce the compliance of the intravesical ureter and permit reflux to occur in situations in which the UVJ is intrinsically of marginal competence (Cook and King, 1979).

Effect of Calculi on Ureteral Function

Factors that affect the spontaneous passage of calculi are (1) the size and shape of the stone (Ueno et al, 1977); (2) intrinsic areas of narrowing within the ureter; (3) ureteral peristalsis; (4) hydrostatic pressure of the column of urine proximal to the calculus (Sivula and Lehtonen, 1967); and (5) edema, inflammation, and spasm of the ureter at the site at which the stone is lodged (Holmlund and Hassler, 1965).

In an attempt to understand the physiologic processes that contribute to or hinder the passage of stones through the ureter, Crowley and associates (1990) created acute ureteral obstruction in the dog with an intraluminal balloon catheter and measured intraluminal ureteral pressures and peristaltic activity above and below the acutely obstructed site. The peristaltic rate and baseline, peak, and delta (peak minus baseline) pressures increased proximal to the site of obstruction. In contrast, the peristaltic rate remained unchanged distal to the obstruction, despite decreases in the baseline, peak, and delta pressures. It was suggested that failure of transmission of effective peristalsis across the site of obstruction may hinder stone passage; however, this remains to be proved. In an experimental study, implantation of an artificial calculus in a rat ureter resulted in an increase in the amplitude of contractions, a decrease in the rate of contractions, and a decrease in baseline pressure (Laird et al, 1997). These changes persisted for a period after spontaneous passage of the calculus. It was suggested that the increased motility caused by a stone contributes to the visceral pain associated with ureteral stone passage.

Two factors that appear to be most useful in facilitating stone passage are an increase in hydrostatic pressure proximal to a calculus and relaxation of the ureter in the region of the stone. In support of the theory that hydrostatic pressure facilitates stone passage, artificial concretions with holes were shown to move more slowly in the rabbit and dog ureter than those without holes (Sivula and Lehtonen, 1967). Furthermore, ureteral ligation proximal to a concretion, which decreases hydrostatic pressure by decreasing urine output and decreases peristaltic activity proximal to a stone, hampers stone passage (Sivula and Lehtonen, 1967).

With respect to the potential facilitative effect of ureteral relaxation on stone passage, spasmolytic agents phentolamine, an α -adrenergic antagonist, and orciprenaline and isoproterenol, β -adrenergic agonists, have been shown to dilate the ureteral lumen or decrease ureteral wall tension at the level of an artificial concretion and thus permit increased fluid flow beyond the concretion (Peters and Eckstein, 1975; Miyatake et al, 2001). In a human study, renal colic was relieved by meperidine in 83% of patients, by phentolamine in 63%, and by propranolol, a β -adrenergic antagonist that presumably would interfere with the β -adrenergic inhibitory actions of catecholamines, in 0% (Kubacz and Catchpole, 1972). These data suggest that drugs with spasmolytic effects on the ureter may relieve renal colic, whereas those with spasmogenic actions do not.

Pharmacologic data can be interpreted to imply that ureteral relaxation in the region of a concretion could aid in stone passage. Agents such as theophylline (Weiss et al, 1977; Green et al, 1987), with strong relaxant effects on the ureter, have potential value in facilitating stone passage. It also has been reported that local aminophylline facilitates ureteroscopy and transureteral lithotripsy (Barzegarneshad et al, 2012) and that endoluminal administration of isoproterenol reduces renal pelvic pressures during flexible ureterorenoscopy (Jakobsen, 2013). In a rabbit in vivo model, rolipram, a cAMP-specific PDE inhibitor (PDE4 inhibitor), caused a more marked ureteral relaxation than did the nonspecific PDE inhibitors papaverine and theophylline, and without the circulatory side effects seen with the nonspecific PDE inhibitors (Becker et al, 1998). Because the relaxant effect of rolipram was similar in human and rabbit in vitro ureteral segments, it was suggested that rolipram could potentially be beneficial in the treatment of renal colic and in the facilitation of stone passage (Becker et al, 1998). Rolipram also has been shown to relax pig intravesical ureteral segments (Hernández et al, 2004). In addition to the PDE4 inhibitor rolipram, PDE5 inhibitors (cGMP-specific PDE inhibitors) relax in vitro pig and human ureteral segments (Kuhn et al, 2000; Al-Aown et al, 2011; Liatsikos et al, 2013). The relaxant effects of PDE4 and PDE5 inhibitors were paralleled by an increase in cAMP and cGMP, respectively. Gratzke and coworkers (2007) showed that PDE5 inhibitors reversed KCl-induced increases in tension of isolated human ureteral segments, with a rank order of efficacy of vardenafil (Levitra) more than sildenafil (Viagra) more than tadalafil (Cialis). Species differences in PDE subtypes may exist. Although the nonspecific PDE inhibitor papaverine decreased the frequency of ureteral peristalsis in the pig, the PDE4 inhibitor, rolipram, had no effect (Danuser et al, 2001).

A combination of the calcium channel blocker nifedipine, which causes ureteral relaxation, and the corticosteroid deflazacort, which reduces edema, was shown to facilitate spontaneous passage of 1 cm or smaller distal ureteral stones (Borghi et al, 1994; Porpiglia et al, 2000). Spontaneous expulsion of 79% of stones (average size 5.8 ± 1.8 mm) occurred in an average of 7 days in patients treated with nifedipine and deflazacort compared with spontaneous passage of 35% of stones (average size 5.5 ± 1.4 mm) within an average of 20 days in untreated patients (Porpiglia et al, 2000). In a subsequent study, the same group showed that both nifedipine and the α -adrenergic antagonist tamsulosin, when combined with deflazacort, increased the rate of spontaneous passage of lower ureteral calculi and that, in addition, tamsulosin, a selective $\alpha_{1A/1D}$ adrenergic receptor antagonist, reduced the time to spontaneous expulsion (Porpiglia et al, 2004, 2006). The researchers showed that tamsulosin alone was effective in facilitating expulsion of distal ureteral stones, and that this effect was potentiated by steroids. Steroids alone were ineffective. α_1 -Adrenergic receptors are present throughout the human ureter, with the greatest quantity of α_1 -adrenergic receptors being in the distal ureter (Sigala et al, 2004, 2005). α_{1D} mRNA was expressed throughout the human ureter, with significantly greater amounts than the α_{1A} - and α_{1B} -receptor subtypes in the proximal and distal ureter. $\alpha_{1A/1D}$ -adrenergic receptors are present in the distal ureter. A number of other studies have noted an increased spontaneous stone expulsion rate and expulsion rate after extracorporeal shock wave lithotripsy (ESWL), a decrease in renal colic, and an improved tolerance of ureteral stents with the administration of tamsulosin and other α -adrenergic antagonists (Cervenakov et al, 2002; Dellabella et al, 2003; Kupeli et al, 2004; Autorino et al, 2005; Gravina et al, 2005; Resim et al, 2005; Yilmaz et al, 2005; De Sio et al, 2006; Gravas et al, 2007; Liatsikos et al, 2007; Damiano et al, 2008; Losek and Mauro, 2008; Al-Ansari et al, 2010; Yencilek et al, 2010; Gurbuz et al, 2011; Lu et al, 2012b). Although most of the studies address the efficacy of tamsulosin in facilitating stone passage, Yilmaz and associates (2005) reported that doxazosin and terazosin were equally effective in facilitating stone passage. Dellabella and colleagues (2005) reported that tamsulosin was more effective than the calcium channel blocker nifedipine in facilitating stone expulsion. Naftopidil, an α_{1D} -adrenergic receptor antagonist, also has

been reported to be effective in facilitating the expulsion of intramural ureteral stones (Lu et al, 2012a).

Effect of Diabetes on Ureteral Function

In patients with diabetes, changes in bladder function affect the ureter. In addition, there is some evidence of a direct effect of diabetes on the ureter. The length and velocity of movement of the urinary bolus is decreased in the streptozotocin (STZ)-induced diabetic rat (Watanabe and Miyagawa, 2002). Although the frequency of contractions of in vitro segments of the renal pelvis and ureter of STZ-induced diabetic rats is unchanged, the amplitude of contractions is increased in comparison with renal pelvic and ureteral segments from control sucrose-induced diuretic rats (Davidson and Lang, 2007). Capsaicin is known to release tachykinins from sensory nerves, and it is postulated that a supersensitivity of the upper urinary tract of STZ-induced diabetic rats to the sensory neurotoxin capsaicin, and to the sensory excitatory neuropeptides substance P and neurokinin A, results from a sensory neuropathy (Davidson and Lang, 2007).

EFFECT OF AGE ON URETERAL FUNCTION

Clinically, the response of the ureter to pathologic conditions varies with age. More marked degrees of ureteral dilatation are observed in the neonate and young child than in the adult. Experimental data corroborating this clinical impression can be derived from observed age-dependent differences in the response of in vitro ureteral segments to an intraluminal pressure load. The neonatal rabbit ureter undergoes a greater degree of deformation in response to an applied intraluminal pressure than does the adult rabbit ureter (Akimoto et al, 1977). Furthermore, norepinephrine decreases the diametral deformation of the neonatal rabbit ureter in response to an applied intraluminal pressure but has little effect on the deformation of the adult rabbit ureter (Fig. 43-27). Thus, the in vitro neonatal rabbit ureter appears to be more compliant and more sensitive to norepinephrine than the adult rabbit ureter.

Age also affects the response of the ureter to β -adrenergic agonists; with aging there is a decrease in the relaxant response to the β -adrenergic agonist isoproterenol (Wheeler et al, 1990). The relaxant response to β -adrenergic agonists is related, in part, to

cAMP levels. It has been shown that with aging there is a decrease in the enzymatic activities involved in the synthesis of cAMP (Wheeler et al, 1986) but no change in the enzymatic activities involved in cAMP degradation (Cho et al, 1988). These data suggest that the decrease in the ability of isoproterenol to relax the ureter with aging is a result of a decrease in the ability of isoproterenol to activate adenylyl cyclase, the enzyme involved in cAMP synthesis. Developmental differences in the response of the ureter to metabolic inhibitors are evident, with cyanide causing a larger decrease in force in the adult than in the neonatal guinea pig ureter (Bullock and Wray, 1998a, 1998b).

A progressive increase in ureteral cross-sectional muscle area is observed in the guinea pig between 3 weeks and 3 years of age. This is in accord with the findings of Cussen (1967), who noted in a human autopsy study (subjects ranging in age from 12 weeks of gestation to 12 years of age) that there is a progressive increase in the population of smooth muscle cells and a small increase in the overall size of the individual smooth muscle cells. In addition, an irregular increase in the number of elastic fibers was observed with increasing age.

The contractility of the ureter also is affected by age. The maximal active force of isolated guinea pig ureteral segments increases between 3 weeks and 3 years of age (Fig. 43-28) (Hong et al, 1980). The increase in force developed between 3 weeks and 3 months of age seems to be attributable to an increase in contractility, because there is an associated increase in active stress (force per unit area of muscle). The increase in force developed between 3 months and 3 years of age can be explained by an increase in muscle mass alone because there is no change in active stress between these two age groups (see Fig. 43-28).

Although changes in the force-length relations of guinea pig ureter occur with age, the force-velocity relations do not change with age (Biancani et al, 1984). Thus, although ureteral contractility increases during early development, as shown by an increase in force per unit area of muscle, or stress, no significant change is apparent in the rate of the driving reactions that control the contractile process—that is, no change in shortening, velocity, work, or power.

EFFECT OF PREGNANCY ON URETERAL FUNCTION

Hydronephrosis of pregnancy begins in the second trimester of gestation and subsides within the first month after parturition. It is more severe on the right side, and the ureteral dilatation does not occur below the pelvic brim. Roberts (1976) has presented a strong case in favor of obstruction as the causative factor in the development of hydronephrosis of pregnancy, whereas other investigators have suggested a hormonal mechanism for the ureteral dilatation of pregnancy (van Wagenen and Jenkins, 1939).

Roberts (1976) emphasized the following: (1) Elevated baseline (resting) ureteral pressures consistent with obstructive changes have been recorded above the pelvic brim in pregnant women, and these pressures decrease when positional changes permit the uterus to fall away from the ureters (Sala and Rubi, 1967). (2) Normal ureteral contractile pressures recorded during pregnancy suggest that hormonally induced ureteral atony is not the prime factor in ureteral dilatation of pregnancy. (3) Women whose ureters do not cross the pelvic brim (i.e., those with pelvic kidneys or ileal conduits) do not develop hydronephrosis of pregnancy. (4) Hydronephrosis of pregnancy usually does not occur in quadrupeds, whose uterus hangs away from the ureters (Traut and Kuder, 1938). (5) Elevated ureteral pressures in the pregnant monkey return to normal when the uterus is elevated from the ureters at laparotomy or when the fetus and placenta are removed from the uterus.

Observed hormonal effects on ureteral function have been used to implicate a hormonal mechanism in the ureteral dilatation of pregnancy, although difficulties in interpretation arise from inconsistencies in the data. Several studies have shown an inhibitory

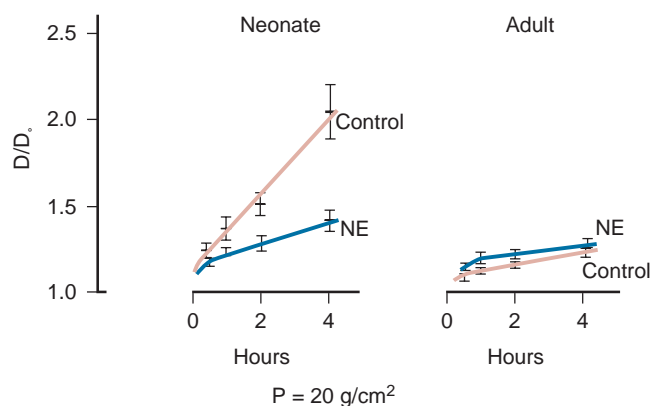

Figure 43-27. Changes in diameter of neonatal and adult rabbit ureteral segments as a function of time after the application of a constant intraluminal pressure (P) of 20 g/cm². Diametral deformation (D/D₀) of control neonatal ureters was significantly greater than that of control adult ureters. Norepinephrine (10⁻⁵ M) decreased the diametral deformation of the neonatal ureters but had no significant effect on the deformation of the adult ureteral segments. D, diameter during deformation; D₀, initial diameter; NE, norepinephrine. (From Akimoto M, Biancani P, Weiss RM. Comparative pressure = length – diameter relationships of neonatal and adult rabbit ureters. Invest Urol 1977; 14:297.)

Figure 43-28. Maximal active (contractile) force and maximal active stress of proximal and distal guinea pig ureteral segments as a function of age.

effect of **progesterone** on ureteral function (Kumar, 1962). Progesterone has been noted to increase the degree of ureteral dilatation during pregnancy and to retard the rate of disappearance of hydro-ureter in postpartum women (Lubin et al, 1941). Other studies, however, have failed to demonstrate an effect of progesterone on ureteral activity in animals (McNellis and Sherline, 1967) or in humans (Lapides, 1948), and still others have failed to induce changes in ureteral activity in women through the administration of estrogens, progesterone, or a mixture of these drugs (Marchant, 1972; Clayton and Roberts, 1973). Although some workers have noted that estrogens increase ureteral activity (Hundley et al, 1942), the majority of investigators have failed to observe an effect of estrogens in animal models (Abramson et al, 1953) or in humans (Kumar, 1962). Thus, **obstruction appears to be the primary factor in the development of hydronephrosis of pregnancy**, although some evidence suggests that a combination of hormonal and obstructive factors is involved (Fainstat, 1963).

EFFECT OF DRUGS ON THE URETER

This section provides an assessment of the effects of the major classes of drugs on ureteral function. Many of the studies referred to were performed in animal models, and extrapolation of the data to the intact human ureter is often difficult. In the clinical situation, the relatively sparse blood supply to the ureter limits the distribution of drugs to the ureter, and the pharmacokinetics are quite different in the laboratory than in the clinic. In addition, many drugs with potential usefulness in the management of ureteral abnormalities have potential untoward side effects when used in concentrations required to affect the ureter.

To assess the effect of drugs on the ureter, it is necessary to understand the anatomic, physiologic, and biochemical properties of the ureter, in addition to understanding the principles of drug action. For a drug to elicit a given response, it is necessary to achieve and maintain an appropriate concentration of that drug at its site of action. Factors that can influence the achievement of an effective concentration of drug at a site of action are (1) the route of

administration and cellular distribution of the drug; (2) the dose of the drug administered; (3) the biotransformation, including metabolism and excretion, of the drug; (4) the binding of the drug to plasma and tissue proteins; and (5) the effects of age and disease on the absorption, distribution, metabolism, and elimination of the drug.

The literature contains considerable confusing and conflicting information concerning the effects of drugs on the ureter. To some extent, the discrepancies in the available data are the result of poorly controlled experimental procedures or of attempts to compare dissimilar functional responses of the ureter with a given drug. To simplify the present section, no attempt is made to analyze the validity of each pharmacologic study or to rationalize discrepancies in the literature; rather, an overview is presented with an attempt to provide a consensus that at times may be prejudiced by personal bias. Furthermore, discussion of drugs related to the nervous system, pregnancy, and a variety of pathologic states is included in earlier sections of this chapter and is not duplicated in this section.

Histamine and Its Antagonists

Histamine has a dual action on smooth muscle; it may (1) release catecholamines from sympathetic nerve endings or (2) act directly on receptors within the smooth muscle. In addition, **histamine may have excitatory or inhibitory effects on ureteral function**. The majority of studies have shown an excitatory effect of histamine on ureteral function (Borgstedt et al, 1962; Sharkey et al, 1965; Ver-ecken, 1973; Benedito et al, 1991; Smita et al, 2006), a finding that may be species dependent (Tindall, 1972). **Histamine's excitatory effect on the ureter and UVJ appears to be mediated by H_1 receptors** because they are inhibited by the H_1 -receptor antagonists mepyramine, pheniramine, and dimethindene but not by the H_2 -receptor antagonists cimetidine and ranitidine (Benedito et al, 1991; Dodel et al, 1996; Smita et al, 2006). An H_1 agonist, 2-(2-pyridyl)ethylamine, increases ureteral contractility (Dodel et al, 1996). The H_1 inhibitor pheniramine has no effect on spontaneous activity of isolated goat ureter (Smita et al, 2006). The excitatory effect of histamine on the sheep UVJ is partially blocked by

scopolamine, suggesting an indirect stimulatory action of histamine on intramural parasympathetic nerves. H₁ histamine receptors are expressed in the smooth muscle and urothelium of the human ureter (Floyd et al, 2008). The antihistamines diphenhydramine (Benadryl) and tripeleminamine have been shown to inhibit the effects of histamine on the ureter (Borgstedt et al, 1962; Sharkey et al, 1965). The H₂ receptor mediates inhibitory effects of histamine. Histamine and the H₂-receptor agonist impromidine relax precontracted ureteral segments, actions that are inhibited by the H₂-receptor antagonist cimetidine (Dodel et al, 1996).

Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) has been reported to stimulate (Vereecken, 1973; Dodel et al, 1996; Hauser et al, 2002; Hernández et al, 2003), inhibit (Mazzella and Schroeder, 1960), or have no effect on (Finberg and Peart, 1970) a variety of ureteral preparations. In the pig ureter the contractile effects appear to be mediated by 5-HT₂ receptors (Hauser et al, 2002; Hernández et al, 2003). Gidener and colleagues (1999) showed that 5-HT induces concentration-dependent contractions of isolated human ureteral segments. However, their studies suggested no involvement of 5-HT₂ receptors in the contractile effects of 5-HT. Tetrodotoxin, guanethidine, and phentolamine had an inhibitory effect on 5-HT-induced contractions of pig isolated intravesical ureteral segments, suggesting that part of the contractile effects of 5-HT are indirectly mediated through release of norepinephrine from sympathetic nerves (Hernández et al, 2003).

Kinins

The kinins—kallidin, elodeisin, and bradykinin—increase the frequency of contraction and baseline intraluminal pressure of the dog ureter (Boyarsky et al, 1966a, 1966b; Labay and Boyarsky, 1966), and bradykinin decreases the contractile force of the sheep ureter (Kaygisiz et al, 1995).

Angiotensin

Angiotensin has a stimulatory effect on the ureter. AT₂ and mRNA for angiotensinogen, a principal precursor of AT₂, renin, angiotensin-converting enzyme (ACE), and the type 1 angiotensin receptor are expressed in the human ureter (Santis et al, 2003). Losartan, an AT₂ receptor antagonist, decreases the amplitude and frequency of spontaneous contractions of human ureteral segments. AT₂ induces phasic contractions of rat ureteral segments, an effect that is inhibited by losartan (Fujinaka et al, 2000). The AT₂ type 1 receptor also is expressed in the rat ureter (Paxton et al, 1993).

Narcotic Analgesics

Morphine has been reported to increase ureteral tone or the frequency and amplitude of ureteral contractions or both in a variety of experimental preparations and in humans (Macht, 1916b; Gruber, 1928; Ockerblad et al, 1935; Vereecken, 1973). Others, however, have failed to observe an effect of morphine on ureteral function (Gould et al, 1955; Kiil, 1957; Weinberg and Maletta, 1961; Ross et al, 1967).

Meperidine (Demerol) appears to have a similar excitatory effect on the activity of the intact dog ureter (Sharkey et al, 1968). Kiil (1957), however, failed to observe an effect of meperidine on ureteral peristalsis in humans. If one considers only the effects on ureteral activity, there is no basis to preferentially favor morphine or meperidine in the treatment of renal colic. Both agents may have ureteral spasmogenic effects that theoretically would detract from their value in the management of ureteral colic. They certainly do not have potentially valuable spasmolytic actions. Their efficacy in treating colic depends on their central nervous system (CNS) actions, which decrease the perception of pain.

Prostaglandins

PGs are derived from fatty acids and have a variety of biologic actions in various systems of the body. Their effects vary with the species, type of PG, endocrine status of the tissue, experimental conditions, and origin of the smooth muscle. The “primary” PGs—PGE₁, PGE₂, and PGF_{2α}—are synthesized from the fatty acid arachidonic acid by enzymatic reactions involving two COX isoforms, COX-1 and COX-2 (Vane, 1998). In most tissues COX-1 is constitutively expressed and is involved in the regulation of normal physiologic processes, whereas COX-2 is induced in response to processes such as inflammation and mitogenesis (Mitchell and Warner, 1999). These enzymatic reactions can be inhibited by indomethacin and aspirin, and by a number of COX-1 and COX-2 inhibitors. COX-1 and COX-2 receptors have been identified in the human ureter (Chaignat et al, 2008).

PGE₂ acts via four G protein-coupled receptors, PTGER₁ to PTGER₄, and PGF_{2α} acts via PTGFR. PTGER₁ and PTGER₃ induce smooth muscle contractions, PTGER₁ via activation of phosphatidylinositol hydrolysis and PTGER₃ via cAMP inhibition. PG receptors PTGER₁ and PTGFR₃ are highly expressed in human ureter urothelium and muscle (Oll et al, 2012). PTGER₂ and PTGER₄ induce smooth muscle relaxation via cAMP stimulation.

PGE₁ inhibits the activity of the dog ureter (Boyarsky et al, 1966b; Wooster, 1971; Abrams and Feneley, 1976) and guinea pig ureter (Vermue and Den Hertog, 1987). PGE₁ inhibition of ureteral activity in the guinea pig is associated with an increase in cAMP levels (Vermue and Den Hertog, 1987). In the ureter, PGE₁ activates adenylyl cyclase, and this may account for the increase in cAMP (Wheeler et al, 1986). Johns and Wooster (1975) suggested that the inhibitory effects of PGE₁ on ureteral activity depended on the sequestration of Ca²⁺ at the inner surface of the cell membrane, with a resultant increase in outward K⁺ conductance and hyperpolarization of the membrane.

Although reports have indicated that PGE₂ relaxes the ureter (Vermue and Den Hertog, 1987), other reports describe an excitatory action of PGE₂ on sheep ureter (Thulesius and Angelo-Khattar, 1985) and human ureter (Angelo-Khattar et al, 1985; Cole et al, 1988) and on renal pelvic smooth muscle (Lundstam et al, 1985). PGE₂ increases the contractility of chronically obstructed human ureters. Although it relaxes normal porcine ureter, it increases the contractility of acutely obstructed porcine ureters (Ankem et al, 2005; Lowry et al, 2005). In contrast to the inhibitory effects of PGE₁ in the dog ureter, PGE₂ increases the frequency of ureteral peristalsis in the dog (Boyarsky and Labay, 1969). In human ureteral preparations, PGE₁ and PGE₂ have been shown to decrease spontaneous contractions, whereas PGF_{2α} increased ureteral contractility (Abrams and Feneley, 1976). In human renal pelvis and ureter there is a higher concentration of PGF_{2α} than PGE₂ (Zwergel et al, 1991). PGF_{2α} increased contractility of porcine ureteral segments (Ankem et al, 2005). The prostanoid PGI₂ is synthesized in the urothelium of the ureter (Ali et al, 1998). COX inhibitors such as indomethacin have been shown to inhibit the activity of rat (Davidson and Lang, 2000), guinea pig (Davidson and Lang, 2000), sheep (Thulesius and Angelo-Khattar, 1985), and human ureters (Angelo-Khattar et al, 1985; Cole et al, 1988) and renal pelvic smooth muscle (Lundstam et al, 1985; Zhang and Lang, 1994; Santicioli et al, 1995a; Davidson and Lang, 2000).

Indomethacin has been used in the management of ureteral colic (Holmlund and Sjöden, 1978; Flannigan et al, 1983; Jönsson et al, 1987). The beneficial effects probably are the result of indomethacin's inhibition of the PG-mediated vasodilatation that occurs subsequent to obstruction (Allen et al, 1978; Sjöden et al, 1982). The vasodilatation theoretically would result in an increase in glomerular capillary pressure and a subsequent increase in pelviureteral pressure. Indomethacin, by reducing pelviureteral pressure and thus pelviureteral wall tension, might eliminate some of the pain of renal colic that is dependent on distention of the upper urinary tract. An upregulation of COX-2 mRNA and protein with obstruction supports the potential use of selective COX-2 inhibitors in the treatment of obstructive ureteral disease (Nakada et al, 2002). A

potential problem with the use of indomethacin for the treatment of renal colic is that PG-mediated vasodilatation aids in preserving renal function; thus, indomethacin may provide pain relief, but it may be potentially deleterious to renal function (Perlmutter et al, 1993; Kristova et al, 2000).

The nonspecific COX inhibitor diclofenac and the selective COX-2 inhibitors NS-398 and celecoxib have been shown to be equipotent in inhibiting agonist-induced contractions of isolated pig and human ureter (Mastrangelo et al, 2000; Nakada et al, 2000), and diclofenac also has been shown to relax human ureteral segments that were precontracted with KCl (Sivrikaya et al, 2003). NS-398 inhibition of ureteral contractility also may involve blockade of voltage-dependent calcium channels (Lee et al, 2010). The COX-2 selective inhibitor celecoxib and indomethacin inhibited porcine ureteral contractility and tumor necrosis factor- α (TNF- α)-induced prostanoid release (Jerde et al, 2005). Diclofenac, but not the COX-2 selective inhibitor valdecoxib, decreased the contractile amplitude of electrically stimulated in vitro human ureteral segments, and valdecoxib decreased the contractility of unobstructed but not obstructed ureters of the pig in vivo (Chaignat et al, 2008). Species differences may exist, with COX-2 being the primary enzyme involved in synthesizing PGs in the guinea pig upper urinary tract, and COX-1 being the primary enzyme involved in PG synthesis in the rat upper urinary tract (Davidson and Lang, 2000).

Chronic obstruction upregulates COX-2 activity in the human ureter (Nakada et al, 2002). With stretch of the porcine ureter, there is COX-2 induction in both the urothelial and smooth muscle layers, with a more significant induction in the urothelium (Jerde et al, 2006). The stretch-induced upregulation of COX-2 expression in the urothelium of the obstructed mouse ureter is mediated via PI3K (Owusu-Ofori et al, 2013). PI3K also mediates stretch-induced activation of PKC (Owusu-Ofori et al, 2013). In the normal rat ureter, COX-1 but not COX-2 mRNA was detected, and after obstruction there was an increase in COX-2 mRNA and protein expression but no change in COX-1 expression (Norregaard et al, 2006). In addition to an increased synthesis of prostanoids with obstruction, there is a decrease in prostanoid degradation contributing to the increase in prostanoids with obstruction. 15-Hydroxyprostaglandin dehydrogenase (PGDH), the enzyme responsible for PG degradation, is suppressed in the human ureter with obstruction (Jerde et al, 2004). The dilated ureter after obstruction has an increased expression of COX-2, PGE₂, TGF- β 1, α -SMA, fibrosis, apoptotic cells, and proliferation cell nuclear antigen (PCNA) (Chuang et al, 2007). The administration of the COX-2 selective inhibitor celecoxib abolished the expression of COX-2 and PGE₂, decreased the expression of TGF- β 1 and α -SMA, decreased apoptotic cells and fibrosis, but increased the expression of PCNA in the smooth muscle of the dilated obstructed ureter (Chuang et al, 2007). These investigators concluded that the COX-2 inhibitor might ameliorate, in part by inhibition of COX-2 and TGF- β 1 expression, ureteral damage resulting from obstruction.

Cardiac Glycosides

Ouabain, a cardiac glycoside, has an effect on ureteral activity that appears to be species dependent. In the isolated cat ureter, ouabain produces a marked increase in contractility, which usually is followed by a late decrease in excitability (Weiss et al, 1970). In the guinea pig ureter, ouabain inhibits activity without a preliminary potentiation of contractility (Washizu, 1968; Hendrickx et al, 1975). The inhibitory effects of ouabain are accompanied by a shortening of the action potential duration, a decrease of the number of oscillations on the plateau of the guinea pig action potential, and a decrease in the RMP.

Calcium Antagonists

Because Ca²⁺ is necessary for the development of the action potential and contraction of the ureter, agents that block the movement of Ca²⁺ into the cell would be expected to depress ureteral function. Voltage-dependent Ca²⁺ channel antagonist

binding sites (receptors) have been demonstrated in the ureter, and their density decreases with age (Yoshida et al, 1992). These dihydropyridine-sensitive, L-type, voltage-dependent Ca²⁺ channels appear to provide the main inward current for generation of the ureteral action potential and the phasic contractile response (Shuba, 1977; Brading et al, 1983; Aickin et al, 1984; Imaizumi et al, 1989; Lang, 1989). Potassium-induced ureteral contractions depend on the inward movement of Ca²⁺ through L-type voltage-dependent Ca²⁺ channels (Maggi and Giuliani, 1995). The dihydropyridine Ca²⁺ channel agonist Bay K8644 has an excitatory effect on ureteral activity (Maggi et al, 1994a; Floyd et al, 2008) and potentiates K⁺-induced contractions. The Ca²⁺ channel blockers verapamil, D-600 (a methoxy derivative of verapamil), diltiazem, and nifedipine have been shown to inhibit ureteral activity (Golenhofen and Lammel, 1972; Vereecken et al, 1975; Hertle and Nawrath, 1984; Hong et al, 1985; Sakanashi et al, 1985, 1986; Maggi et al, 1994a; Davenport et al, 2006). These inhibitory effects are accompanied by decreases in the duration of the action potential, the number of oscillations on the plateau of the guinea pig action potential, excitability, and the rate of rise and amplitude of the action potential. High concentrations of verapamil and D-600 cause a complete cessation of electrical and mechanical activity.

Potassium Channel Openers

Potassium channel openers such as cromakalim, nicorandil, BRL 38227, and PFK 217-744b hyperpolarize smooth muscle membranes and inhibit renal pelvic and ureteral activity (Kontani et al, 1993; Maggi et al, 1994b; Weiss et al, 2002; Smita et al, 2006; Floyd et al, 2008). Glibenclamide, a blocker of K⁺-ATP channels, on its own had no effect on contractility (de Moura and de Lemos Neto, 1996). The inhibitory effects of cromakalim and nicorandil are prevented by glibenclamide, providing evidence that ATP-sensitive K⁺ channels are involved in these processes (Maggi et al, 1994b; Smita et al, 2006). Activation of these K⁺ channels may reduce the probability of the opening of voltage-sensitive Ca²⁺ channels, inhibit agonist-induced increases in IP₃, or reduce Ca²⁺ sensitivity of contractile elements—processes that are important in the generation of the ureteral action potential and the contractile response (Cook and Quast, 1990; Quayle et al, 1997).

The tricyclic antidepressant amitriptyline (Elavil) has been shown to relax isolated pig and human ureteral strips by opening potassium channels (Achar et al, 2003). This relaxation response is inhibited by 4-aminopyridine (4-AP), a voltage-dependent K⁺ channel blocker. Nicorandil, a K⁺ channel opener and NO donor, stimulates guanylyl cyclase activity with formation of cGMP and hyperpolarizes the smooth muscle with resultant relaxation of rabbit, guinea pig, and human ureter (Klaus et al, 1989, 1990; Weiss et al, 2002). The relaxant effects of nicorandil can be inhibited by both the K_{ATP} antagonist glibenclamide and the guanylyl cyclase inhibitor methylene blue (Weiss et al, 2002).

Endothelins

Endothelins are potent vasoconstrictor peptides that exist in three isoforms: ET-1, ET-2, and ET-3. These peptides interact with their specific receptors: ET_A, ET_B, and ET_C. Endothelin binding sites (receptors) have been identified in the ureter and renal pelvis (Eguchi et al, 1991; Latifpour et al, 1995; Wada et al, 2001), where they are primarily of the ET_A subtype (Latifpour et al, 1995; Wada et al, 2001). Endothelins have been shown to initiate contractions in isolated guinea pig and porcine ureters (Eguchi et al, 1991; Maggi et al, 1992a) and increase the contractile force of renal pelvis smooth muscle (Wada et al, 2001). ET-1 acting on the ET_A receptor increased contractile force of rat renal pelvis smooth muscle (Grisk et al, 2010). COX-1 and Rho-kinase (ROCK) activity are required for ET-1 effects on renal pelvic contractility. ET-1, ET-2, and ET-3 increased tonic contractions and intraluminal pressures in isolated human ureteral segments. These actions were inhibited by BQ-123, an ET_A receptor antagonist, and BQ-788, an ET_B receptor antagonist. ET-1 and ET-3 inhibited spontaneous phasic activity of the isolated

human ureteral segments, an action that was not blocked by either ET_A or ET_B receptor antagonists (Jankovic et al, 2011). Diabetes upregulates the expression of ureteral endothelin receptors (Nakamura et al, 1997).

Antibiotics

Ampicillin causes relaxation of the ureter and antagonizes the stimulatory effects of barium chloride ($BaCl_2$), histamine, serotonin, and carbachol on the ureter, thus suggesting that its action is directly on the smooth muscle (Benzi et al, 1970b). Chloramphenicol, the isoxazolyl penicillins, and gentamicin also have spasmolytic effects on the ureter (Benzi et al, 1970a, 1971, 1973). The tetracyclines, on the other hand, potentiate the contractile effects of $BaCl_2$ on the ureter (Benzi et al, 1973).

Renal Physiology

Renal physiology impacts the urologic care of patients in numerous ways. These can include the pathophysiology of surgical disease (renal tubular acidosis [RTA] and malignant paraneoplastic syndromes), the modification of surgical technique (ischemia-reperfusion injury and intrarenal surgery), or iatrogenic complications of surgery (hyponatremia and metabolic complications of urinary diversions). The purpose of this chapter is not to turn urologists into nephrologists, but rather to provide a firm fundamental knowledge of renal physiology and pathophysiology to provide the foundation for urologic-specific conditions and therapies.

RENAL PHYSIOLOGY

Vascular (Renal Blood Flow and Glomerular Flow Rate)

Renal Blood Flow

Renal blood flow (RBF) is regulated by changes in vascular resistance of all the arteries up to and including the efferent arteriole, which in turn is regulated by a variety of neurohormonal signals (see later).

Blood enters the kidney through the renal arteries and divides into progressively smaller arteries (interlobar, arcuate, and interlobular arteries) until it enters the glomerular capillary through the afferent arteriole. A portion of the plasma that enters the glomerulus is filtered across the glomerular membrane; this is called the *filtration fraction*. The rest of the blood exits the glomerular capillary through the efferent arteriole. In nephrons located in the renal cortex, these capillaries travel in close proximity to the tubules and modulate solute and water reabsorption. In juxtamedullary nephrons (located deeper in the medulla), the efferent arterioles branch out to form vasa recta, which participate in the countercurrent mechanism through which urine is highly concentrated and body water conserved (see later discussion).

Under normal resting conditions, RBF is 20% of total cardiac output. Total blood flow is different for men and women, averaging 982 ± 184 mL/min in women and 1209 ± 256 mL/min in men (Dworkin and Brenner, 2004). Renal plasma flow (RPF) is slightly less, averaging 592 mL/min in women and 659 mL/min in men, and it varies with hematocrit ($RPF = RBF \times [1 - Hct]$). RBF is not evenly distributed to all parts of the kidney. Flow to the outer cortex is two to three times greater than that to the inner cortex, which in turn is two to four times greater than that to the medulla (Dworkin and Brenner, 2004).

Determinants of Glomerular Filtration

The most important function of the kidney is the process of **glomerular filtration**. Through the passive ultrafiltration of plasma across the glomerular membrane, the kidney is able to regulate total body salt and water content, to regulate electrolyte composition, and to eliminate waste products of protein metabolism.

The process of filtration is analogous to fluid movement across any capillary wall, and is governed by Starling forces. The

Renal Pathophysiology

glomerular filtration rate (GFR) is thus determined by both hydraulic and oncotic pressure differences between the glomerular capillary and the Bowman space, as well as by the permeability of the glomerular membrane:

$$GFR = LpS \times (\Delta \text{hydrostatic pressure} - \Delta \text{oncotic pressure})$$

where Lp = glomerular permeability and S = glomerular surface area.

The rate at which filtration occurs within an individual nephron is termed the “single nephron GFR” (SN-GFR). A more relevant measurement is that of total GFR, which is the sum of all SN-GFR and is expressed in milliliters per minute. **GFR is thus a reflection of overall renal function.** Alterations in GFR can occur either with alterations in any aspect of Starling forces, or through a change in RPF.

1. *Transglomerular (hydraulic) pressure (TGP)*—the most significant determinant of GFR is the TGP. Although systemic arterial pressures impact TGP, the glomerular capillary is unique in that it is interposed between two arterioles (the afferent and efferent arterioles) and thus can regulate intraglomerular capillary pressure (IGP) independent of systemic pressures through changes in afferent and efferent arteriolar tone. In normal circumstances, the pressure within the Bowman space is essentially zero, and only in conditions of urinary obstruction does the pressure increase to clinically significant levels. Thus the $TGP = IGP$.
2. *Renal plasma flow*—increases in RPF lead to increases in GFR. Although the filtration fraction cannot exceed 20% in normal circumstances, an increase in RPF will lead to an increase in absolute GFR.
3. *Glomerular permeability*—generally, an increase in permeability does not lead to an increase in GFR, because the glomerulus is already at maximal permeability for water and other relevant solutes. It may, however, lead to increased filtration of larger molecules not normally filtered, such as albumin. Reductions in permeability, or in glomerular surface area, can lead to reductions in GFR.
4. *Oncotic pressure*—the least relevant of all the variables. Under normal circumstances, plasma proteins are not filtered across the glomerular membrane and so oncotic pressure within the Bowman space is essentially zero.

Regulation of Glomerular Filtration Rate

Under normal circumstances, GFR is tightly maintained at a relatively constant level, despite large fluctuations in systemic arterial pressures and RBF. This is accomplished through the processes of autoregulation and tubuloglomerular feedback.

1. *Autoregulation*—with increases in mean arterial pressure (MAP), afferent arteriolar tone increases to minimize increases in IGP. Similarly, with reductions in MAP, afferent arteriolar tone decreases to allow increased flow into the glomerulus to maintain IGP, thus maintaining GFR. Autoregulation of IGP is effective to a MAP of about 70 mm Hg; below that, reductions in MAP lead to similar reductions in GFR, and below a MAP of

40 mm Hg, filtration ceases. The mechanism(s) by which autoregulation is achieved is not well understood. It is likely mediated through myogenic stretch receptors in the afferent arteriole wall, possibly mediated by adenosine triphosphate (ATP) (Schnermann and Levine, 2003), but angiotensin II is also involved with more severe fluctuations.

2. **Tubuloglomerular feedback (TGF)**—cells in the macula densa monitor tubular ultrafiltrate flow rates. If SN-GFR increases, delivery of sodium cations (Na^+) and chloride anions (Cl^-) to the distal tubule also increases. This increased Cl^- delivery triggers a response by the macula densa, which ultimately leads to an increase in afferent arteriolar tone and subsequent decrease in RPF, thus returning SN-GFR (and tubular flow) back to baseline (Schnermann et al, 1998). Thus TGF can be thought of as a mechanism to minimize salt and water losses through the regulation of GFR. The mediators of this response are not well understood, but it seems that angiotensin II plays a permissive role in TGF. Both adenosine and thromboxane can cause afferent arteriolar vasoconstriction and have been implicated in TGF. Nitric oxide (NO) (Schnermann and Levine, 2003) is also believed to be important, particularly in minimizing TGF in the setting of increased NaCl intake.

Under abnormal conditions, however, neurohumoral responses become more important. With significant reductions in effective circulating volume (ECV), both norepinephrine and angiotensin II play important roles in maintaining GFR through arteriolar vasoconstriction, often at the expense of reduced RPF. Notably, renal prostaglandins (PGs) and NO offset afferent arteriolar vasoconstriction; so arteriolar tone is a balance between the vasoconstrictive and the vasodilatory effects of the previously mentioned hormones. Inhibition of PG synthesis (because of the administration of non-steroidal anti-inflammatory drugs [NSAIDs]), particularly in states of high angiotensin II production, can lead to severe vasoconstriction and acute reduction in GFR. In contrast, norepinephrine and angiotensin II levels are diminished in states of volume expansion, whereas dopamine and atrial natriuretic peptide (ANP) levels are increased to facilitate an increase in RPF (dopamine) and natriuresis (ANP), thus returning volume status back to normal.

Clinical Assessment of Glomerular Filtration Rate

Unfortunately, GFR cannot be measured directly. It can, however, be estimated by a variety of methods, some more accurate (but usually more cumbersome) than others.

Renal Clearance. The best estimate of GFR can be obtained by measuring the rate of clearance of a given substance from the plasma. However, to be accurate, the substance to be measured must meet certain criteria. It must:

- Be able to achieve a stable plasma concentration,
- Be freely filtered across the glomerulus,
- Not be secreted, reabsorbed, synthesized, or otherwise metabolized by the renal tubules, and
- Not be impacted by any other means of removal from the plasma.

If all these criteria are met, then:

$$\text{Filtered X} = \text{excreted X}$$

and since

$$\text{Filtered X} = \text{GFR} \times \text{plasma [X]}$$

and since

$$\text{Excreted X} = \text{urine [X]} \times \text{urine volume (in mL/unit time)}$$

we can now see that

$$\text{GFR} \times \text{plasma [X]} = \text{urine [X]} \times \text{urine volume}$$

$$\text{GFR} = \text{urine [X]} \times \text{urine volume} / \text{plasma [X]}$$

This is called the *clearance* of a substance and reflects the amount of plasma that is completely cleared of the substance per unit time. There are a number of substances that have been used clinically to estimate GFR.

1. **Inulin**—is a fructose polysaccharide that meets the necessary requirements, and inulin clearance is believed to be the best measure of GFR. However, it is not clinically useful because it is difficult to administer (requires an intravenous [IV] infusion of inulin) and is difficult to measure.
2. **Radiolabeled compounds**—such as iothalamate or diethylenetriaminepentaacetic acid (DTPA). These clearances are also very accurate, but are again limited in clinical use by their cost and availability (Perrone et al, 1990).
3. **Creatinine**—the most widely used estimate of GFR is the 24-hour creatinine clearance (CrCl) (Levey, 1990). It uses endogenous creatinine, which is produced at a constant rate. The rate of production varies from individual to individual, but for a single individual, daily variability is less than 10%. It has advantages in that it is easy to perform (no IV infusion), is relatively cheap, and is readily available. However, it is less accurate than inulin clearance, because some creatinine is cleared from plasma through proximal tubular secretion; thus a CrCl overestimates true GFR by an average of 10% to 20%. This becomes even more important as GFR declines, because tubular secretion increases in response to increasing serum creatinine levels and may contribute up to 35% of all creatinine removal at GFR levels of 40 to 80 mL/min (Shemesh et al, 1985). Thus at best the CrCl should be considered the “upper limit” of the true GFR.

Plasma Markers. An even simpler method to estimate GFR is with the use of plasma levels of substances that can be used as surrogate markers of GFR. To be useful, the substance must fulfill the criteria outlined previously. Three such substances have been used:

1. **Plasma creatinine (PCr)**—the most widely used plasma marker of GFR. Although creatinine production is constant within an individual from day to day, there is marked variation in production rates between individuals. The absolute rate depends on muscle mass, which in turn is influenced by age, sex, and body mass. Thus there is no single “normal” PCr that reflects a “normal” GFR; it must be individualized for every person. This can be accomplished through mathematical manipulation (see later). However, the relationship of PCr to GFR is relatively constant (Fig. 44-1), and thus changes in PCr can be used to predict corresponding changes in GFR. As a general rule, every 50% reduction in GFR results in a doubling of PCr. There are limitations to the use of the PCr, which should be noted:
 - As GFR falls, tubular secretion of creatinine increases; so PCr may not change noticeably until there has been a significant drop in GFR (Shemesh et al, 1985).
 - Creatinine production may increase in states of increased muscle breakdown (e.g., rhabdomyolysis) or with increased dietary protein intake or supplementation, leading to an underestimation of true GFR.

Figure 44-1. Relationship between serum creatinine and creatinine clearance. PCr, plasma creatinine.

- Creatinine production may decrease with liver cirrhosis, leading to an overestimation of true GFR.
2. *Plasma urea*—another widely used plasma marker. Urea production and excretion are highly variable, influenced, for instance, by dehydration, high-protein diets, and increased tissue breakdown. As a result, it is a much less reliable marker of GFR than is the PCr and should not be used as the sole determinant.
 3. *Plasma cystatin C*—an endogenous protein found in all nucleated cells. It has a constant rate of production unaffected by diet, and clearance is not influenced by tubular functions (Filler et al, 2005). This test is not widely available at present.

Mathematical Correction. There are a number of mathematical formulas that have been developed to improve the accuracy of the PCr estimation of GFR (National Kidney Foundation, 2002). The three most widely used are the Cockcroft-Gault, “modification of diet in renal disease” (MDRD), and CKD-EPI formulas.

1. *Cockcroft-Gault*: originally developed from data collected from individuals with normal renal function; it is a simple formula to estimate CrCl (not GFR) that corrects for age, sex, and body mass (ideal body weight [IBW]) (Cockcroft and Gault, 1976). The formula is

$$\text{CrCl} = \frac{\{(140 - \text{age}) \times (\text{IBW in kg})\}}{[\text{PCr (mg/dL)} \times 72]} \times 0.85 (\text{women})$$

It has the advantage of being very simple, but it is not as accurate as other methods when renal function is impaired.

2. *MDRD formulas*: a series of formulas derived from data collected in patients with severe renal impairment; these formulas are more complex but more accurate than the Cockcroft-Gault. The simplest estimate of GFR is the four-variable equation (PCr, age, sex, and ethnicity) (Manjunath et al, 2001):

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 186 \times (\text{PCr [mg/dL]})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \times (1.210 \text{ if African American})$$

3. *Chronic kidney disease epidemiology collaboration (CKD-EPI) formula*: derived from data collected in patients with a wide range of renal function; it is a more accurate estimate of GFR in patients with normal or only mildly reduced kidney function. It has largely replaced the MDRD formula in clinical practice (Levey et al, 2009):

$$\text{GFR} = 141 \times \min(\text{SerumCreat/kappa}, 1)^{\alpha} \times \max(\text{SerumCreat/kappa}, 1)^{-1.209} \times 0.993^{\text{Age}} \times \text{Sex} \times \text{Race}$$

For females, the following values are used: Sex = 1.018; alpha = -0.329; kappa = 0.7

For males, the following values are used: Sex = 1; alpha = -0.411; kappa = 0.9

For race, black = 1.159; all others = 1

In summary, the GFR is analogous to renal function. Total GFR is a summation of all SN-GFR, which in turn are determined primarily by TGP and glomerular permeability of the individual nephrons, and it is usually tightly regulated. A GFR estimate should be obtained in all patients with renal impairment (rather than a PCr alone), and the recommended method is through the use of the CKD-EPI formula, the four-variable MDRD formula, or the Cockcroft-Gault formula.

Hormonal

Control of Renal Vascular Tone

Vascular tone of the renal vessels, the net balance of vasoconstrictive and vasodilatory forces, is crucial to the maintenance of RBF, GFR, tubular renal function, and systemic blood pressure. **There is**

BOX 44-1 Vasoactive Substances That Control Renal Artery Tone

VASOCONSTRICTION

Angiotensin II
Norepinephrine
Vasopressin
Endothelin
Atrial natriuretic peptide

VASODILATION

Nitric oxide
Carbon monoxide
Prostaglandin E₂
Acetylcholine
Serotonin/bradykinin
Glucocorticoids

KEY POINTS: RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

- GFR reflects total renal function.
- CrCl can approximate GFR.
- Formulas based on patient's age, weight, and serum creatinine can best estimate GFR.

a complex network of hormones and vasoactive substances with both direct and indirect effects, resulting in a system that is pleiotropic and redundant. Although much has been learned from animal models about the function of individual molecules, the complexity of the total system can lead to unexpected outcomes when individual pathways are manipulated pharmacologically. A summary of substances known to impact vascular tone is provided in Box 44-1.

Vasoconstrictors

Angiotensin II. Angiotensin II is a potent vasoconstrictor. In the kidney, there is a more pronounced constrictive effect on the efferent than the afferent arteriole, because of the inhibition of angiotensin II actions in the afferent arteriole by NO and PG (Arima, 2003). Elevated levels of angiotensin II are important for maintaining GFR in pathologic conditions that reduce RBF (e.g., renal artery stenosis, dietary sodium restriction). The classic effects of angiotensin II (vasoconstriction, aldosterone release, sodium retention) are mediated by the AT₁ receptor (Kaschima and Unger, 2003). The AT₂ receptor, however, may cause intrarenal dilation and be protective against renal ischemic injury (Carey, 2005).

Norepinephrine. Norepinephrine vasoconstricts all the major vascular beds in the kidney, mediated through the α₁ receptor. In patients who receive norepinephrine as a pressor agent in the face of systemic vasodilation, renal function is preserved and may actually improve (Albanese et al, 2004).

Endothelin. Endothelin is the most potent vasoconstrictor yet identified. There are three isoforms, with ET-1 being the most fully described. An endothelin precursor (big ET-1; 39 amino acids) is cleaved to ET-1 (21 amino acids) by an endothelin-converting enzyme found on the endothelial cell membrane. The endothelin receptors are subclassified into ET (A), which are purely vasoconstrictive, and ET (B). The ET (B) receptors may cause either vasodilation by stimulating the release of NO from endothelial cells, or vasoconstriction of vascular smooth muscle cells (Fellner and Arendshorst, 2004). ET-1 release is stimulated by angiotensin II, antidiuretic hormone, thrombin, cytokines, reactive oxygen species, and shearing forces acting on the vascular endothelium. ET-1 release is inhibited by NO, as well as by prostacyclin and ANP. Blockade of the ET (A) receptor can reduce renal vasoconstriction

seen in such ischemic conditions as ureteral obstruction (Bhangdia et al, 2003).

ET-1 has a number of other actions besides vasoconstriction. ET-1 stimulates aldosterone secretion, produces positive inotropy and chronotropy in the heart, decreases RBF and GFR, and releases ANP. Despite reduction in RBF, sodium excretion is increased, suggesting that ET may be responsible for maintaining sodium balance when the renin-angiotensin system is depressed (Perez del Villar et al, 2005). Medullary blood flow is preserved in the face of endothelin-induced vasoconstriction, which may explain the relative stimulation of tubular functions (Evans et al, 2004).

Vasopressin. Vasopressin acts directly on blood vessels through the vasopressin V1 receptor but does not directly change RBF at low doses (Malay et al, 2004). Vasopressin does potentiate the vasoconstrictive effects of norepinephrine (Segarra et al, 2002) and can induce renal ischemia at high doses. At the low doses typically used in the management of septic shock, renal function is preserved (Holmes et al, 2001).

Atrial Natriuretic Peptide. Atrial natriuretic peptide (ANP) is a vasoactive hormone synthesized primarily by the atria in response to stretching, as occurs during physiologic levels of volume expansion (Fig. 44-2). The primary actions of ANP on the kidney are increased GFR and natriuresis. ANP can increase GFR without a change in RBF (Sward et al, 2005) by the combination of afferent arteriolar vasodilation and efferent arteriolar vasoconstriction. In addition, ANP dilates vessels that have been precontracted by norepinephrine, angiotensin II, or vasopressin. ANP production increases during bilateral obstructive uropathy, which may be one mechanism of preserving GFR (Kim et al, 2002).

ANP increases natriuresis mainly through the inhibition of sodium reabsorption in the medullary-collecting duct (Zeidel et al, 1988); decreased renin and decreased aldosterone production may also play a role (Laragh, 1985). Clinically, however, infusion of low-dose ANP during surgery increases water and electrolyte excretion without measured systemic changes in cortisol, angiotensin II, or aldosterone (Koda et al, 2005). This approach has also been used to prevent ischemic renal damage in high-risk cardiac surgery (Sward et al, 2004).

Vasodilators

Nitric Oxide. NO is a highly reactive gas that participates in multiple physiologic and pathophysiologic reactions in the body. NO is synthesized from the reaction between arginine, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and oxygen to produce citrulline, NADP, water, and NO. A family of enzymes called *nitric oxide synthase* (NOS) catalyzes this reaction. Although all NOS enzymes catalyze the same reaction, they differ in distribution, expression, and stimuli. Neuronal (nNOS, NOS-1) and endothelial (eNOS, NOS-3) are constitutively expressed, and iNOS

(NOS-2) is inducible. eNOS is found in the vascular endothelium, and the NO produced there plays a key role in vasodilation and vascular remodeling (Rudic et al, 1998). eNOS expression is stimulated by shear stress by activation of the tyrosine kinase c-SRC (Davis et al, 2004), by heat shock protein 90 (Harris et al, 2003), by oxidant stress (Cai et al, 2001), and by vascular mediators such as bradykinin, serotonin, adenosine, adenosine diphosphate/adenosine triphosphate, histamine, and thrombin (Arnal et al, 1999).

After its formation by vascular endothelial cells, NO diffuses to vascular smooth muscle cells where it activates soluble guanylyl cyclase (sGC), producing 3',5'-cyclic guanosine monophosphate (cGMP). Subsequently, cGMP activates both cGMP- and 3',5'-cyclic adenosine monophosphate (cAMP)-dependent protein kinases (PKG and PKA, respectively) leading to smooth muscle relaxation. eNOS blockade increases renal vascular resistance and decreases the glomerular ultrafiltration coefficient (Gabbai, 2001). NO also helps maintain vascular integrity, with increased expression being linked to decreased neointimal formation and medial thickening (Kawashima et al, 2001). Indeed, the degenerative changes seen in chronic allograft nephropathy related to cyclosporine use can be mitigated by increased NO expression (Chander et al, 2005). Increased eNOS activity is also associated with protection from renal ischemia-reperfusion injury (Shoskes et al, 1997).

Although raised local levels of NO from eNOS can be beneficial to renal function, induction of iNOS and overproduction of NO from inflammatory cells can be deleterious. In the face of free oxygen radicals at the site of inflammation, NO can interact with reactive oxygen species to form peroxynitrite, which induces protein damage by formation of nitrotyrosine. Increased iNOS has been related to damage from nitrotyrosine in glomerular disease (Trachtman, 2004), lupus nephritis (Takeda et al, 2004), and transplant rejection (Albrecht et al, 2002). Increased iNOS activity has direct renal effects as well, including upregulation of sodium and bicarbonate tubular transport (Wang, 2002).

Carbon Monoxide. Carbon monoxide (CO) gas is another reactive diffusible mediator with multiple effects throughout the body, especially in the kidney. Heme oxygenase (HO), an essential enzyme in heme catabolism, catalyzes the rate-limiting step in heme degradation, resulting in the formation of iron, CO, and biliverdin (Hill-Kapturczak et al, 2002). Biliverdin is subsequently converted to bilirubin by biliverdin reductase. HO is expressed in two forms, constitutive HO-2 and inducible HO-1. Increased CO production produces vasodilation in the kidney and can counteract catecholamine-induced vasoconstriction (Mustafa and Johns, 2001). In particular, both HO-1 and HO-2 are highly expressed in the medulla and help maintain renal medullary blood flow (Zou et al, 2000). In cirrhosis, decreased renal expression of HO-1 is

Figure 44-2. The fundamental biologic processes of atrial natriuretic peptide (ANP). AII, angiotensin II.

linked to renal dysfunction (Miyazono et al, 2002). CO also regulates sodium transport in the loop of Henle, with HO-2 blockade inhibiting sodium excretion (Wang et al, 2003) and stimulation increasing natriuresis and diuresis (Rodriguez et al, 2003).

The other primary effect of CO in the kidney is renoprotection from oxidant injury. CO includes documented anti-inflammatory, antioxidant, and cytoprotective actions (Sikorski et al, 2004). Indeed, a patient with a genetic HO-1 deficiency exhibited significant tubular and vascular endothelial injury (Ohta et al, 2000). Increased CO is protective against ischemia-reperfusion injury in native and transplant kidneys (Nakao et al, 2005). Induction of HO-1 through agents such as bioflavonoids protects against tubular damage and improves renal transplant function (Shoskes et al, 2003).

KEY POINTS: HORMONAL

- Multiple chemical mediators act on renal vascular tone, which controls RBF.
- Endothelin is the most potent vasoconstrictor.
- NO and CO are potent vasodilators.

Erythropoiesis

Red blood cell (RBC) production is a tightly regulated process. Basal RBC production is roughly 10 RBCs/hr, but this rate can be greatly increased during times of anemia or hypoxia. The kidney is the major organ involved in this process, and it is responsible for monitoring RBC levels and increasing RBC output through the production of the hormone erythropoietin.

Erythroid Progenitor Cells. Mature RBCs are produced from a small pool of multipotent progenitor cells (Suda et al, 1984), which in turn are derived from the fetal liver. The earliest committed cell is the erythroid burst-forming unit (BFU-E), which, under appropriate stimulation, divides to produce erythroid colony-forming units (CFU-E). Further differentiation leads to the production of proerythroblasts, reticulocytes, and, ultimately (after extrusion of the nucleus), mature RBCs. The entire process requires about 2 weeks.

Erythropoietin. Maturation of the BFU-E and CFU-E depends on the appropriate growth factors. The most important of these factors is erythropoietin (EPO). The kidney is responsible for the majority of EPO production (90%), whereas the liver may contribute a smaller amount (10%). Kidney-derived EPO is produced by a subpopulation of interstitial fibroblasts, and possibly proximal tubular cells, in response to decreased O_2 tension.

EPO-deficient mice die in utero with a marked reduction in erythropoiesis (Munugalavada and Kapur, 2005). Additional growth factors such as interleukin-3, GM-CSF, stem cell factor, activin, insulin-like growth factor (IGF-I), and, possibly, hepatic growth factor act synergistically with EPO to reduce apoptosis and thus promote proliferation of erythroid cells (Muta and Krantz, 1993).

EPO has also been shown to have effects outside of the bone marrow. EPO receptors have been demonstrated in kidney, brain, retina, heart, skeletal muscle, and endothelial cells (Juul et al, 1998). In the kidney, pretreatment with high-dose EPO has been shown to reduce ischemia-reperfusion injury in animal models, because of decreased apoptosis (Patel et al, 2004).

Regulation of Erythropoietin Production and Erythropoiesis. Production of EPO, and hence erythropoiesis, is closely associated with circulating O_2 tension. Under hypoxic conditions, the alpha subunit of the regulatory protein hypoxia-inducible factor-1 (HIF-1) is exposed (Wang et al, 1995). Binding of HIF-1 alpha with HIF-1 beta, hepatic nuclear factor-4 (HNF-4), and p300 turns on EPO transcription (Arany et al, 1996). After the hypoxia has been corrected, HIF-1 alpha is ubiquitinated and rapidly degraded by proteosomes, thus shutting down EPO production. There is also in vitro evidence that hypoxia itself might directly increase erythropoiesis through HIF-1-mediated increases in autocrine motility factor (AMF) production and subsequent decrease in apoptosis (Mikami et al, 2005).

In states of chronic inflammation, erythropoiesis is decreased. Apoptosis of erythroid progenitor cells occurs in the presence of the tumor-associated antigen RCAS1, which is also produced by macrophages under inflammatory conditions (Suehiro et al, 2005).

In certain malignancies, such as renal cell carcinoma, erythropoiesis is enhanced because of a mutation in the von Hippel-Lindau (VHL) gene. As a result, there are constitutively increased levels of HIF-1 and polycythemia (Wiesener et al, 2002).

Erythropoiesis is also decreased in most forms of chronic renal failure, and subsequently anemia is common in the later stages of the disease. This is because of decreased EPO levels as a result of a reduction in the number of functional EPO-producing cells within the kidney. Recombinant human erythropoietin (rHuEPO) has been shown as an effective treatment for this type of anemia.

rHuEPO has also been used to treat anemia associated with malignancy, but it must be used with caution in these conditions because its use may be associated with an increased risk of venous thromboembolism and higher mortality (Bennett et al, 2008).

Bone Mineral Regulation

Normal regulation of bone mineralization, through maintenance of serum calcium and phosphorus levels, is achieved through the actions of vitamin D, parathyroid hormone (PTH), and fibroblast growth factor-23 (FGF-23). The actions of these hormones are exerted largely through the kidney (Fig. 44-3).

Vitamin D Regulation. The kidney plays an important role in the regulation of vitamin D activity. The major source of vitamin D is through dermal synthesis of the precursor compound cholecalciferol (vitamin D_3), or through dietary intake of vitamin D_3 -fortified foods. Vitamin D_3 has minimal biological activity and requires two hydroxylations to become active. The first

Figure 44-3. Effects of vitamin D and parathyroid hormone (PTH) on calcium homeostasis. ECF, extracellular fluid. (From Yu SLY. Renal transport of calcium, magnesium, and phosphate. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 536.)

occurs in the liver through the action of 25-hydroxylase to form 25-hydroxycholecalciferol (calcidiol). The calcidiol molecule is bound to vitamin D-binding protein and transported to the kidney, where it is filtered and reabsorbed by renal tubular cells. A second hydroxylation occurs within the tubular cell. Because these cells contain both 1α -hydroxylase and 24α -hydroxylase, hydroxylation will produce either inactive 24,25-dihydroxycholecalciferol or 1,25-dihydroxycholecalciferol (calcitriol), the biologically active form that is 100 times more potent than calcidiol. Calcitriol production is regulated by calcidiol levels as well as the 1α -hydroxylase levels. In turn, PTH and plasma phosphate levels (increased enzyme activity) and serum calcitriol levels (decreased enzyme activity) determine these (Portale et al, 1989). However, unregulated calcitriol synthesis can occur in macrophages in granulomatous conditions such as sarcoidosis and tuberculosis, and in prostate epithelial and cancer cells (Young et al, 2004).

Vitamin D Activity. Calcitriol functions through a single intracellular vitamin D receptor (VDR) to regulate gene transcription (Lowe et al, 1992). Its primary function is the maintenance of serum calcium and phosphorus levels. The four main target organs are the intestine (increases intestinal absorption of calcium, and, to a lesser extent, phosphorus), the bones (regulates osteoblast activity, and, in combination with PTH, allows for osteoclast activation and bone resorption), the kidney (increases reabsorption of calcium), and the parathyroid gland (suppresses PTH release). Evidence suggests that both calcidiol and calcitriol may also function as antiproliferative agents. Prostate epithelial and cancer cells demonstrate VDR, and vitamin D may suppress the growth of these cells, especially in combination with androgens (Tuohimaa et al, 2005).

In summary, vitamin D contributes to normal bone mineralization by maintaining normal serum calcium and phosphorus levels through increased intestinal absorption of calcium and phosphorus and increased renal reabsorption of calcium.

Parathyroid Hormone Regulation. Synthesis, secretion, and degradation of PTH are influenced directly by serum calcium levels through calcium-sensing receptors located on parathyroid cells. During periods of hypocalcemia, PTH synthesis and secretion are increased while degradation is decreased. The opposite occurs during hypercalcemia. In addition, calcitriol has a suppressive effect on PTH synthesis and parathyroid cell proliferation, mediated through vitamin D receptors located on the surface of parathyroid cells. Hyperphosphatemia also directly stimulates PTH release, primarily in advanced renal insufficiency. Finally, other cations such as magnesium and aluminum have slight stimulatory effects, likely mediated through the calcium-sensing receptors.

Parathyroid Hormone Activity. PTH exerts its activity through PTH/PTHrP receptors, which are localized primarily in the kidneys and bone.

Bone. The effect of PTH on bone metabolism depends on its administration; if given continuously, it stimulates bone resorption and increases serum calcium and phosphorus levels. Administered intermittently, it leads to increased bone formation and mineral density.

Kidney. The renal effects of PTH are threefold. First, it increases active calcium reabsorption at the level of the distal tubule (Friedman and Gesek, 1993). Second, it decreases phosphate reabsorption in the proximal convoluted tubule (PCT) (and the distal tubule, to a lesser degree) through its action on the sodium-phosphorus cotransporter (Pfister et al, 1997). Third, it stimulates calcitriol production by increasing 1α -hydroxylase levels while decreasing 24α -hydroxylase levels (Broadus et al, 1980).

In summary, PTH functions to maintain normal serum calcium and phosphorus levels by increasing bone resorption, by increasing renal reabsorption of calcium and excretion of phosphorus, and by stimulating production of calcitriol.

Fibroblast Growth Factor-23 Regulation. FGF-23 is a peptide secreted primarily by bone osteoclasts. It plays a key role in regulating serum phosphate levels through its actions on the kidney and parathyroid gland. High plasma phosphate levels and increased circulation calcitriol levels stimulate FGF-23 production. It exerts its activity through its receptor protein Klotho (Urakawa et al, 2006).

Fibroblast Growth Factor-23 Activity. FGF-23 increases phosphate excretion in the kidney by reducing the number of Na-Pi cotransporters in the PCT (Miyamoto et al, 2007). It also suppresses the activity of 1α -hydroxylase, thus decreasing calcitriol production (Saito et al, 2003). FGF-23 also acts on the parathyroid gland, reducing PTH production (Ben-Dov et al, 2007).

In summary, FGF-23 functions to maintain plasma phosphate levels through the regulation of renal phosphate excretion and both calcitriol and PTH production.

Antidiuretic Hormone

Antidiuretic hormone (ADH), or arginine vasopressin as it is called in humans, is a polypeptide secreted by the posterior pituitary gland. It functions to maintain serum osmolality and volume through the regulation of free-water excretion in the kidney.

Antidiuretic Hormone Actions

ADH increases the passive reabsorption of water at the level of the collecting duct. Through interaction with the V2 receptor, it facilitates the insertion of preformed water channels, known as aquaporin-2 (AQP-2), into the luminal membrane of the principal cells (Agre et al, 2002). This allows luminal water to enter the cell and then diffuse back into the systemic circulation through the basolateral membrane of the cell (Fig. 44-4). ADH increases urea reabsorption in the medullary collecting tubule through specific urea transporters, which helps maintain the high interstitial osmolality required for water reabsorption. ADH also increases systemic vascular resistance through interaction with the V1 receptor; this is of minor physiologic importance. Other effects of ADH include increased sodium reabsorption and potassium excretion, increased PG synthesis, increased adrenocorticotrophic hormone secretion (through V3 receptors), and release of both factor VIII and von Willebrand factor from vascular endothelium.

Control of Antidiuretic Hormone Secretion. There are two major stimuli for ADH release; these are hyperosmolality and decreased ECV, as well as a number of less common factors (Table 44-1).

Hyperosmolality. The major extracellular osmole is sodium; so for practical purposes, ADH release is governed by changes in serum sodium concentrations. Serum osmolality is monitored by osmoreceptors in the hypothalamus, and changes as little as 1% are enough to affect ADH release (Robertson, 1987).

Decreased Effective Circulating Volume. Circulating volume is monitored by pressure (baro-) receptors in the carotid sinus, which stimulate ADH release in response to reductions in ECV. These receptors are much less sensitive than the osmoreceptors, and as such, ADH release is not affected until there is a noticeable drop in MAPs (usually around 10% to 15% blood volume loss) and after other vasoconstrictive hormones, such as renin and norepinephrine, have been activated.

Other Stimuli. There are a number of other factors that can increase ADH secretion (see Table 44-1). Nausea and pain are probably the most clinically relevant, and as a result, postsurgical hyponatremia resulting from excessive ADH release is a potentially life-threatening problem.

When both decreased ECV and hyponatremia coexist, the pressure receptors usually override the osmoreceptors and prevent the inhibition of the ADH secretion that is usually seen with hyponatremia (Baylis, 1987). This is clinically relevant in conditions of decreased ECV and hyponatremia, such as congestive heart failure where ADH secretion persists despite significant hyponatremia.

Renal Tubular Function

Basic Functions

The renal tubule has two basic functions: *reabsorption* (transport of substances from lumen to blood) and *secretion* (transport of

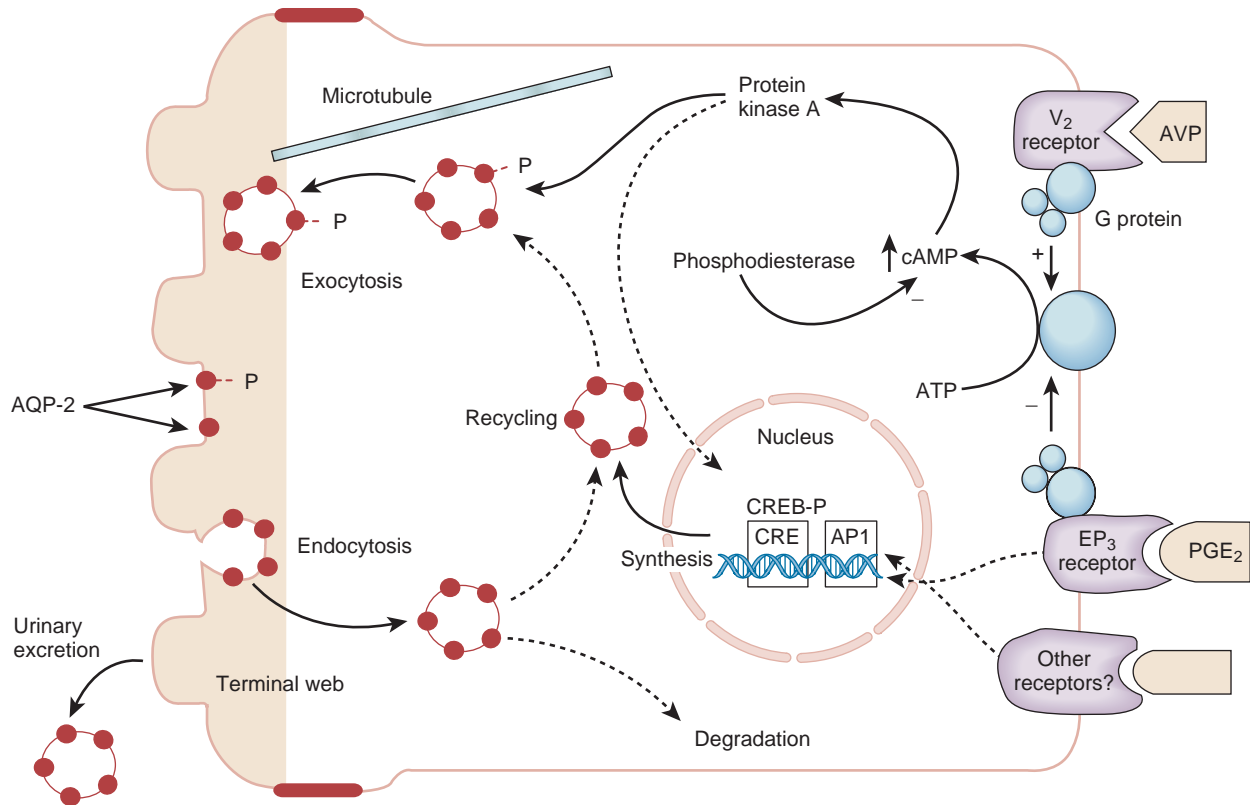

Figure 44-4. Action of antidiuretic hormone on aquaporin (AQP) transport. AP1, transcription factor; AVP, arginine vasopressin; cAMP, cyclic adenosine monophosphate; CRE, cAMP response element; CREB-P, CRE-binding protein; EP₃, prostaglandin receptor; PGE₂, prostaglandin E₂. substances from blood to lumen). Transport can involve one of two pathways: either *transcellular* (across the luminal and basolateral membrane) or *paracellular* (between cells) (Fig. 44-5). Each section of the tubule (Fig. 44-6) is specialized to facilitate absorption and secretion of certain substances through a variety of transport mechanisms.

Proximal Convoluted Tubule

The PCT is responsible for reabsorption of 60% of the glomerular filtrate. In normal circumstances, it reabsorbs 65% of the filtered sodium, potassium, and calcium; 80% of filtered phosphate, water, and bicarbonate; and 100% of the filtered glucose and amino acids (Moe et al, 2004). The PCT is able to increase or decrease

Figure 44-5. Example of transcellular transport between the tubule cell and the basolateral membrane. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 425.)

reabsorption in response to changes in GFR to maintain constant reabsorptive fractions through the process of *glomerulotubular balance*. The early (S1 and S2) segments of the PCT mainly accomplish this. The later (S3) segment is responsible for secretion of numerous drugs and toxins that are too large, or protein bound,

Figure 44-6. Organization of the renal tubule. (From Knepper MA, Gamba F. Urine concentration and dilution. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 601.)

to be filtered. As well, the PCT is responsible for the generation of ammonia from glutamine, which is necessary for urinary acidification.

Sodium. The majority of sodium reabsorption occurs in the PCT, and it occurs through both secondary active and passive mechanisms (Fig. 44-7).

1. *Secondary active reabsorption*—luminal Na^+ moves passively into tubular cells; this movement, however, is driven by osmotic and electrochemical gradients between the luminal and intracellular environments established by the energy-requiring Na^+ - K^+ -ATPase located in the basolateral cell membrane. There is an active exchange of three intracellular Na^+ for two extracellular K^+ ions, which keeps the intracellular sodium concentration low and the cell interior negative with respect to the lumen. This is called *secondary passive reabsorption*. Na^+ then enters the cell through coupled transport with other solutes (see later) or in exchange for H^+ through a Na^+ - H^+ antiporter. The activity of this transporter is under neurohormonal regulation and can be influenced by angiotensin II, norepinephrine, and dopamine to either increase or decrease Na^+ reabsorption in response to changes in ECV.
2. *Passive reabsorption*—this occurs when Na^+ moves paracellularly into the intercellular space. It is mediated through Cl^- transport across the paracellular pathway, which creates an electrochemical gradient favoring Na^+ movement out of the lumen into the intercellular space.

In summary, sodium is the most significant solute for the PCT for three reasons:

- It is the only solute that is actively reabsorbed (through the basolaterally located $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump).
- All other solutes are passively reabsorbed through Na^+ -coupled transport.
- Early reabsorption of Na^+ (as well as other solutes) creates an osmotic gradient that facilitates passive reabsorption of water.

Potassium. The majority of potassium reabsorption occurs by the paracellular route. It is largely dependent on sodium and fluid movement, as potassium reabsorption parallels that of water and sodium.

Bicarbonate. The majority of filtered bicarbonate (90%) is reclaimed in the PCT. There is no upper limit to bicarbonate reabsorption; in states of volume depletion and increased proximal reabsorption of Na^+ , bicarbonate reabsorption continues even in

Figure 44-7. Mechanisms of sodium reabsorption in the proximal tubule. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 414.)

the presence of significant alkalemia (Moe et al, 2004). Bicarbonate is not transported across PCT cells; its reabsorption is dependent on H^+ secretion by the Na^+/H^+ antiporter. Within the lumen, bicarbonate combines with H^+ to form H_2O and CO_2 , which can diffuse intracellularly and be converted back to H^+ and bicarbonate and can subsequently be secreted through the basolateral membrane by a Na^+ -coupled transporter and returned to the circulation. Both of these reactions are catalyzed by carbonic anhydrase (Fig. 44-8).

Water. Water reabsorption in the PCT is a passive process, driven by the reabsorption of other solutes and the subsequent osmotic gradient that develops between the lumen and intercellular space. The majority of water reabsorption occurs in the late PCT. As with Na^+ movement, water can also move either transcellularly or paracellularly. Transcellular movement accounts for 80% of water reabsorption, and it occurs through the specialized water channel aquaporin-1 (AQP-1) (Agre et al, 2002). Paracellular movement accounts for only 20% of water reabsorption and occurs across the tight junctions between cells.

Glucose. Glucose reabsorption is driven by passive Na^+ reabsorption. In the early (S1 and S2) PCT, this occurs through a high-capacity, low-affinity Na^+ /glucose transporter called SGLT-2 (Moe et al, 2004). In the later (S3) segment of the PCT, reabsorption occurs through a low-capacity, high-affinity $2Na^+$ /glucose transporter (also found in intestine) called SGLT-1. Intracellular glucose is then transported out of the cell through the basolateral membrane by the facilitative transporter GLUT-2. Under normal plasma glucose levels, all filtered glucose is reabsorbed. However, if plasma levels exceed 200 mg%, then the filtered load will exceed the reabsorptive threshold and urinary glucose will be detected (Fig. 44-9).

Proteins and Amino Acids. Amino acid transport is complex. Generally, there are separate transporters for the basic, acidic, and neutral amino acids, and most are Na^+ dependent. There are a few amino acids that have specialized transporters, and some are Na^+ independent. Larger proteins are usually catabolized by brush border peptidases and reabsorbed as amino acids; some, however, enter the cell through carrier-mediated endocytosis.

Phosphate. About 85% to 90% of filtered phosphate is reabsorbed, primarily in the PCT. Phosphate reabsorption occurs through a Na^+ -phosphate cotransporter. Plasma phosphate levels, parathyroid hormone, and FGF-23 regulate the activity of this transporter (Fig. 44-10).

Calcium. Most calcium reabsorption occurs in the late S2 segment and in the early S3 segment of the PCT. It is a passive process, driven by the lumen (+) potential difference (PD). Calcium movement occurs by the paracellular route, through the specific calcium

channel claudin-2 (Amasheh et al, 2002), located in the tight junctions. It is also possible that there is a small amount of active calcium reabsorption in the late S3 segment, but this is poorly characterized (Fig. 44-11).

Magnesium. About 15% of filtered magnesium is reabsorbed in the PCT, but the mechanism is poorly understood (Konrad et al, 2004).

Loop of Henle

The loop of Henle consists of four segments; the thin descending limb (DLH), the thin ascending limb (ALH), the medullary thick

Figure 44-9. Absorption of glucose by the renal tubule. GLUT, glucose transporter; SGLT, sodium glucose-linked transporter. Figure 44-11. Absorption of calcium by the renal tubule. CNT, connecting tubule; DCT, distal convoluted tubule; PT, proximal tubule; TAL, thick ascending limb. (From Yu SLY. Renal transport of calcium, magnesium, and phosphate. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 538.)

ascending limb (mTALH), and the cortical thick ascending limb (cTALH). It receives the 40% of ultrafiltrate not reabsorbed by the PCT. Each segment of the loop of Henle has specific functions related to fluid, electrolyte, and acid-base balance, but the major function of the loop, as a whole, is to reabsorb 25% to 30% of the filtered Na⁺ and to reabsorb NaCl in excess of water to establish an extremely concentrated medullary interstitium, which is necessary for the excretion of a concentrated final urine. The loop of Henle, like the PCT, is also controlled by glomerulotubular balance, which maintains a consistent ultrafiltrate delivered to the collecting ducts (Fig. 44-12).

Thin Descending Limb. The DLH consists of the segment of the nephron between the end of the PCT (S3 segment) and the bottom of the loop. Cortical nephrons, in general, have short DLHs, whereas juxtamedullary nephrons have longer DLHs. There is very little active transport of any kind within the DLH, but it has very high water permeability because of abundant expression of AQP-1 (Agre et al, 2002).

Thin Ascending Limb. The ALH begins at the loop and continues up to the thick ascending limb. The ALH is of variable length; cortical nephrons may have little ALH. Similar to the DLH, there is no active transport of solutes. However, unlike the DLH, the AHL is water impermeable. There is high permeability for NaCl as well as urea; so reabsorption of these solutes occurs passively along an osmotic gradient, because the luminal concentrations of these solutes is high because of water removal during transit through the DLH.

Thick Ascending Limb. The TALH is far more active in terms of solute reabsorption than either of the thin limbs. Water reabsorption, however, is negligible because this segment of the loop is entirely impermeable to water because of the lack of aquaporins.

Sodium, Potassium, and Chloride. The TALH reabsorbs 25% to 30% of the sodium filtered across the glomerulus. This is primarily through the secondary active process driven by basolateral Na⁺-K⁺-ATPase pumps that keep intracellular sodium concentration low. Na⁺ is transported transcellularly by a Na⁺/K⁺/2Cl⁻ (NKCC2) transporter located in the apical membrane. After transportation to the inside of the cell, Cl⁻ is pumped out across the basolateral membrane by a Cl⁻/K⁺ cotransporter, which helps keep intracellular chloride concentration low. K⁺, however, preferentially exits the cell back through the apical membrane K channel ROMK and reenters the tubular lumen, where it can interact again with the NKCC2 transporter. **This K⁺ recycling is important; without it, sodium reabsorption would be limited by the luminal potassium concentration, which is much lower**

Figure 44-12. Anatomy of the loop of Henle. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 431.)

than either sodium or chloride concentrations. By recycling K⁺, the tubule is able to reabsorb sodium independent of potassium. A secondary benefit of this process is to help establish a lumen (+) PD, which helps facilitate paracellular transport of a variety of cations, including sodium (Fig. 44-13).

The NKCC2 transporter is the site of the action of loop diuretics. These drugs bind to the Cl⁻ receptor and interfere with normal transporter action, resulting in decreased NaCl reabsorption and subsequent diuresis.

Sodium reabsorption along the TALH, in the absence of water reabsorption, is critical to the formation of the interstitial concentration gradient. This gradient is essential to subsequent urinary concentrating ability in the collecting duct. It also creates a progressively more hypotonic ultrafiltrate, which is important for water diuresis to occur (see later).

Calcium and Magnesium. About 15% of the filtered calcium is reabsorbed in the TALH. Reabsorption is passively driven by the lumen (+) PD by the paracellular route, facilitated by the calcium channel paracellin-1 (also known as claudin-16). Magnesium reabsorption (60% to 70%) also occurs in the TALH in a similar manner

Figure 44-13. Paracellular transport of cations in the thick ascending limb. ATP, adenosine triphosphate; ROMK, renal outer medullary potassium channel. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 433.)

(Konrad et al, 2004). Inhibition of the NKCC2 transporter with loop diuretics induces renal calcium and magnesium wasting because of dissipation of the lumen (+) PD.

Bicarbonate. The TALH also reabsorbs 10% to 20% of the filtered bicarbonate, mainly through H^+ secretion by using the Na^+/H^+ exchanger. Water reabsorption occurring in the DLH increases bicarbonate reabsorption by increasing luminal bicarbonate concentrations.

Countercurrent Mechanism. A critical function of the kidney is the preservation of body water; this is accomplished through the osmotic reabsorption of solute-free water in the collecting tubule (see later) and the excretion of urine that is hyperosmolar with respect to plasma. Human kidneys can produce a urine concentration of up to 1200 mOsm/kg. To achieve this degree of urinary concentration, the kidney must be able to generate an interstitial osmotic gradient of similar degree. Through the process of *countercurrent multiplication*, the loop of Henle is able to produce an interstitial osmotic gradient ranging from 285 mOsm/kg (isosmotic with plasma) in the outer medulla to 1200 mOsm/kg in the inner medulla. The basic steps of countercurrent multiplication are as follows:

1. Medullary interstitium is made hyperosmolar by the reabsorption of NaCl (in the absence of water reabsorption) in the ascending limbs of the loop of Henle.
2. Because of the hairpin (*countercurrent*) configuration of the loop, the concentration of the luminal fluid can be progressively increased (*multiplied*) to as much as 1200 mOsm/kg (Fig. 44-14). This allows the interstitial osmolality to increase to similar levels.
3. In the presence of ADH, urea diffuses from the medullary collecting tubule into the interstitium, increasing the interstitial osmolality even further (Yang and Bankir, 2005). This includes a secondary benefit of increasing water reabsorption in the DLH, thus increasing luminal sodium and chloride concentrations in the ascending limbs and making step 1 even more efficient (Fig. 44-15).

Figure 44-14. Countercurrent mechanism in the renal tubule. AD, antidiuresis; WD, water diuresis. (From Knepper MA, Gamba F. Urine concentration and dilution. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 604.)

Figure 44-15. Role of active NaCl transport in initiating countercurrent multiplication. In step 1, at time zero, the fluid in the descending and ascending limbs and the interstitium is isosmotic to plasma. In step 2, NaCl is transported out of the ascending limb into the interstitium to a gradient of 200 mOsm/kg. In step 3, the fluid in the descending limb equilibrates osmotically with the hyperosmotic interstitium, primarily by water movement out of the tubule. Dilution of the interstitium by this water movement is prevented by continued NaCl transport out of the ascending limb. The result is the creation of an osmotic gradient between the ascending limb and the relatively hyperosmotic descending limb and interstitium.

4. Because of the high interstitial osmolality, water is passively reabsorbed in the medullary collecting tubule (in the presence of ADH). This could potentially lead to dilution of the interstitium. To minimize this effect, the volume of ultrafiltrate is minimized through water reabsorption in the cortical collecting tubule. Also, the vasa recta are arranged in a similar hairpin loop that allows water removal but minimizes removal of interstitial solutes (Pallone et al, 2003).

The osmotic gradient can be disturbed in certain clinical conditions. Increased medullary blood flow (as seen with osmotic diuresis) increases removal of interstitial solutes through the vasa recta

and leads to a lower interstitial osmolality. In addition, prolonged use of loop diuretics will prevent the transport of NaCl in the ascending limb of the loop of Henle, necessary for the ongoing maintenance of the interstitial hyperosmolality; hence, prolonged water diuresis may be seen after discontinuation of the drug, until the gradient can be reestablished.

Tamm-Horsfall Mucoprotein. The TALH is also the site of secretion of Tamm-Horsfall mucoprotein, or uromodulin. It is clinically important, because it forms the matrix of all urinary casts. It has been shown to be important in the prevention of urinary tract infections (Bates et al, 2004). It has also been implicated in the pathogenesis of cast nephropathy, medullary cystic renal disease, and familial juvenile hyperuricemic nephropathy.

Distal Tubule

The distal tubule is primarily involved in sodium and calcium reabsorption. There may be some capacity for H^+ and K^+ secretion, but the importance of this is unknown. The distal tubule can be subdivided into two sections, the distal convoluted tubule (DCT), and the connecting tubule (CNT).

Sodium and Chloride. The DCT reabsorbs another 5% to 10% of the sodium filtered through the glomerulus. As in the TALH, it is a secondary active process, driven by basolateral Na-K ATPase pumps, that occurs in the absence of water reabsorption. Na^+ is reabsorbed electroneutrally with Cl^- by a Na^+/Cl^- (NCC) cotransporter that can be inhibited with the thiazide diuretics. Additionally, there may be some Na^+ reabsorption by the Na^+/H^+ exchange transporter in the luminal membrane. Notably, Na^+ reabsorption in the DCT is regulated by luminal sodium concentration but not by hormonal influences. Hence, anything that increases delivery of Na^+ to the DCT will lead to increased Na^+ reabsorption in this section of the tubule. One clinical example would be the use of loop diuretics. By inhibiting the NKCC2 transporter in the TALH, Na^+ delivery increases to the DCT. In response, there is usually a marked increase in Na^+ reabsorption, which may significantly diminish the diuretic response achieved with the loop diuretic. Such a response may be minimized by concomitant use of a thiazide diuretic.

The connecting segment can also reabsorb sodium, but it does so under the influence of aldosterone, which is similar to what occurs in the principal cells of the cortical collecting tubule.

Calcium. The DCT accounts for 10% to 15% of calcium reabsorption. Unlike either the PCT or loop of Henle, calcium reabsorption in the DCT is independent of Na^+ reabsorption. Calcium enters the cell through the luminal calcium channel TRPV5 and binds to the intracellular binding protein calbindin D_{28} (Loffing and Kaissling, 2003). By doing so, free intracellular calcium concentration is kept low, thus facilitating inward movement of calcium. Extrusion from the cell occurs through the basolateral membrane using either a Ca^{2+}/H^+ (PMCA) or Na^+/Ca^{2+} (NCX) exchanger (Loffing and Kaissling, 2003). In contrast to the PCT or loop of Henle, movement of calcium by the paracellular route is inhibited because of the presence of the protein claudin-8, which markedly decreases calcium permeability through tight junctions.

Calcium reabsorption is regulated in this region by the actions of PTH and, to a lesser degree, calcitriol (vitamin D). PTH increases calcium reabsorption, possibly through alterations in intracellular voltage as a result of increased Cl^- flux through the basolateral membrane. Calcitriol is thought to increase the number of TRPV5 channels and increase calbindin production, both of which would increase calcium reabsorption (Chamoux et al, 2010; Haussler et al, 2013).

Magnesium. A total of 5% to 10% of filtered magnesium is actively reabsorbed in the DCT by the transcellular route. This likely occurs through the luminal magnesium channel TRPM6 (Voets et al, 2004) and is driven by a basolateral Na^+-Mg^{2+} pump that generates a Mg gradient favoring inward flow of Mg.

Collecting Tubule

The collecting tubule consists of two parts, the cortical collecting tubule (CCT) and the medullary collecting tubule (MCT). Whereas

the more proximal portions of the nephron are designed for bulk reabsorption of ultrafiltrate, the collecting tubules are responsible for the final qualitative changes in ultrafiltrate composition in response to dietary intake.

Cortical Collecting Tubule

The CCT consists of two distinct cell types, each with distinct functions. Principal cells (65%) are generally involved in NaCl reabsorption, whereas intercalated cells (35%) are mostly involved with acid secretion. Both are also involved in K regulation.

Principal Cells

Sodium, Potassium, and Chloride. Sodium reabsorption occurs passively through the luminal Na channel ENaC rather than through a cotransporter system (Loffing and Kaissling, 2003). Basolateral Na^+-K^+ -ATPase pumps keep intracellular sodium concentration low, facilitating inward movement of sodium. Movement of sodium intracellularly, without an accompanying anion, creates a lumen (-) PD that results in either passive paracellular movement of Cl^- out of the lumen, or secretion of intracellular K into the lumen to restore electroneutrality. Sodium reabsorption is regulated in the CCT primarily by aldosterone, which increases the number of open ENaC. Blockade of the Na channel by the diuretic amiloride leads to reduced Na reabsorption as well as K secretion, as the electrochemical gradient is eliminated, and thus the driving force for K secretion is abolished (Fig. 44-16). Prostaglandin E_2 (PGE_2) also seems to inhibit Na reabsorption, and reduction of PGE_2 by NSAIDs leads to sodium retention.

Figure 44-16. Effect of blockade of the Na channel by the diuretic amiloride. ATP, adenosine triphosphate. (From Moe OW, Baum M, Berry CA, Rector FC Jr. Renal transport of glucose, amino acids, sodium, chloride, and water. In: Brenner BM, editor. Brenner and Rector's the kidney. 7th ed. Philadelphia: Saunders; 2004. p. 439.)

K secretion in the CCT depends not only on aldosterone-sensitive inward Na movement, but also on luminal flow rates. When flow decreases in the tubular lumen, local intraluminal potassium concentration increases and minimizes the favorable potassium gradient, thus minimizing secretion. This can be partially offset by the actions of ADH, which increase potassium secretion, possibly by the insertion of new K channels in the luminal membrane or by increased Na reabsorption (Wang, 1995). Thus any condition that leads to decreased luminal flow rates, or increased aldosterone production, can lead to reduced potassium excretion.

Water. The water permeability of the CCT is low in the basal state. However, it can be greatly increased in the presence of ADH. This is a result of the insertion of preformed AQP-2 water channels into the luminal membrane (Agre et al, 2002), which allows water to be passively reabsorbed and to equilibrate with the cortical interstitium through basolateral AQP-3 and AQP-4 channels. This is important for the development of highly concentrated final urine, because it decreases the volume of ultrafiltrate delivered to the MCT, where most of the final concentration of urine occurs (Knepper et al, 1994) (Fig. 44-17).

Intercalated Cells. There are two different types of intercalated cells, with different functions: type A intercalated cells, involved mostly with H⁺ secretion; and type B intercalated cells, involved mostly with bicarbonate secretion.

Hydrogen and Bicarbonate. In both cell types, intracellular H₂O, under the influence of carbonic anhydrase, is combined with CO₂ to produce H⁺ and HCO₃⁻. Also, in both cell types, H⁺ and HCO₃⁻ are secreted from the cell by similar transporters. However, the location of the transporters differs.

Type A intercalated cells include both H⁺-ATPase and H⁺-K⁺-ATPase pumps located on the luminal membrane, which facilitate H⁺ secretion into the tubular lumen. Bicarbonate is transported back to the systemic circulation by a HCO₃⁻/Cl⁻ transporter on the basolateral side of the cell. The net effect is the acidification of the urine and the subsequent increase in extracellular pH. As expected, this process is stimulated with the conditions of acidemia. Aldosterone seems to have a permissive effect on this, probably through actions on the H⁺-ATPase pump, because increased urine H⁺ loss and subsequent systemic alkalosis is seen in conditions of hyperaldosteronism.

Type B intercalated cells have similar transporters, but their polarity is reversed. That is, the H⁺-ATPase pumps are located on the basolateral side of the cell, whereas the HCO₃⁻/Cl⁻ transporters are localized to the luminal membrane. The result is a net loss of bicarbonate and a decrease in systemic pH. This result is necessary in states of alkalemia and it thus functions to lower systemic bicarbonate.

Potassium. Although there is normally a net secretion of potassium in the CCT, there is the potential for potassium reabsorption through the H⁺-K⁺-ATPase. This becomes more relevant in states of potassium depletion, when the activity of these pumps is increased. Although this may serve to help correct systemic hypokalemia, it is often at the expense of increased H⁺ secretion and resultant systemic alkalosis.

Medullary Collecting Tubule

The MCT is divided into the outer MCT (oMCT) and inner MCT (iMCT). Both segments contain cells similar to the principal cells and intercalated cells found in the CCT; hence, the handling of sodium, potassium, hydrogen ion, and bicarbonate is similar. The main functional difference lies with the MCT's water and urea permeabilities and thus its ability to concentrate the urine to levels far greater than that of plasma.

Water and Urea. The MCT is relatively impermeable to water in the basal state, but under the influence of ADH, permeability increases in both the iMCT and oMCT by the insertion of AQP-2 water channels. This allows water to move out of the tubule into the hyperosmolar interstitium, and urine concentration occurs. Equally important to this process is urea. The oMCT is relatively impermeable to urea, both in the basal state and under ADH stimulation. In contrast, the iMCT has a high basal permeability for urea, resulting largely from specific urea transporters (UT-A1 and UT-A3) located on the basolateral cell membrane, and also, to a lesser extent, the luminal membrane. Short-term regulation is under the influence of ADH, which can increase urea permeability as much as fourfold through an increased number of urea transporters. Longer-term regulation can be affected by protein intake. This allows a high concentration of urea to develop in the interstitium, thus sustaining the osmotic gradient that is responsible for water reabsorption and ultimately urinary concentration (Yang and Bankir, 2005).

KEY POINTS: RENAL TUBULAR FUNCTION

- The nephron has different functional segments that control homeostasis.
- Most resorption of bicarbonate and ions occurs in the proximal tubule.
- The architecture of the loop of Henle allows a highly hypertonic interstitium to develop, which is crucial to maximal urinary concentration.

Figure 44-17. The components of the normal urine dilution mechanisms. (Redrawn from Berl T, Schrier RW. *Water metabolism and the hypo-osmolar syndrome*. In: Brenner BM, Stein JH, editors. *Sodium and water homeostasis*. New York: Churchill Livingstone; 1978. p. 1-23.)

Sodium. As mentioned earlier, Na reabsorption in the MCT is similar to that occurring within principal cells in the CCT. However, it has been shown that Na reabsorption is diminished in the MCT under conditions of volume expansion. This in part is because of the actions of ANP, which decreases Na reabsorption in the iMCT but not the oMCT. This effect seems to be a result of a reduction in the number of open Na channels in the luminal membrane.

RENAL PATHOPHYSIOLOGY

Sodium and Water Imbalances

Imbalances of sodium and water are often poorly managed and are misunderstood by clinicians, despite well-documented mechanisms and appropriate therapy. The most consistent clinical misconception is that sodium concentration reflects total body sodium content. Because sodium is primarily extracellular, the serum concentration reflects water balance. Therefore hyponatremia can occur in the face of total body sodium excess, and hypernatremia can occur with sodium deficits. For an imbalance to occur, there must be an imbalance between sodium and water that is not handled by

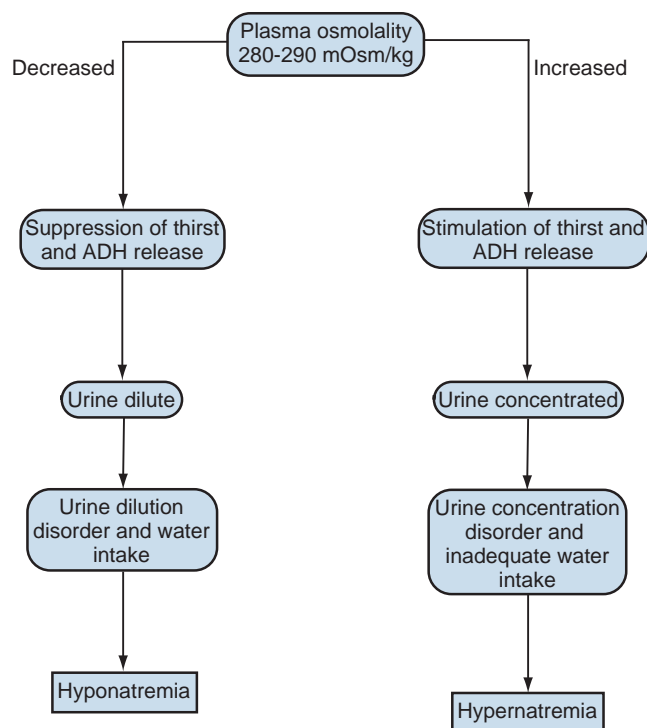

Figure 44-18. Flowchart illustrating the development of disorders of water metabolism. ADH, antidiuretic hormone.

the normal mechanisms of response. Therefore the way to approach serum sodium abnormalities is to determine the water status of the patient and then to determine why the normal compensatory mechanisms have failed (Fig. 44-18).

Hyponatremia

By definition, hyponatremia exists if there is a water excess relative to extracellular sodium that has not been handled by the normal compensatory mechanisms of thirst suppression and decreased ADH release, leading to a serum sodium less than 135 mEq/L. Hyponatremia is seldom symptomatic unless severe (<120 mEq/L), but when it is severe and/or of sudden onset, it can produce seizures, altered mental state, coma, and death. Most commonly, hyponatremia occurs because the kidney is unable to excrete solute-free urine (Mallie et al, 1997). To calculate the amount of water excreted or retained by the kidney, it is useful to consider that urine has two components: one that contains all of the solute in an isotonic solution (termed C_{osm} or osmolar clearance) and another that contains only solute-free water (termed $C_{\text{H}_2\text{O}}$ or free-water clearance). The total urine volume (V) (e.g., liters per day) is the sum of C_{osm} and $C_{\text{H}_2\text{O}}$:

$$V = C_{\text{osm}} + C_{\text{H}_2\text{O}}$$

When the urine is hypo-osmotic to plasma, $C_{\text{H}_2\text{O}}$ is a positive value. Hyponatremia occurs when one or more of these requirements are not fulfilled, such as when GFR is reduced, when diuretics impair NaCl reabsorption, or when vasopressin is in excess (e.g., SIADH). If water intake exceeds the kidney's capacity to form solute-free water (>10 to 20 L/day), hyponatremia also occurs. This abnormality in solute-free water clearance in hyponatremic patients is reflected by the failure to excrete maximally dilute urine ($U_{\text{osm}} = 100$ mOsm/kg).

The diagnosis of hyponatremia is made by measurement of serum electrolytes. There are, however, several conditions in which a low serum sodium level is misleading. The reported lab value is

usually in terms of sodium per volume of plasma, rather than water. If large molecules, such as lipids or protein, are present in large quantities, they decrease the amount of water in a given volume of plasma, but these molecules contribute little to plasma osmolality. What is truly important is the amount of osmotically active solute per volume of water. Pseudohyponatremia is most commonly seen with abnormal elevations of serum lipids or glucose. For every 1 g/dL-increase in triglycerides, measured sodium is decreased by 2 mEq/L, and for every 100 mg/dL of glucose, measured sodium is decreased by 1.6 mEq/L.

Therefore the approach to a patient with true hyponatremia begins with an assessment of volume status (Fig. 44-19). Clinical features such as skin turgor, orthostatic hypotension, jugular venous distension, ascites, and respiratory crackles can all be helpful in this decision. Patients who are clinically hypovolemic by definition will experience a sodium deficit greater than their water deficit. The appropriate renal response would be to excrete urine that is hypo-osmotic with a high $C_{\text{H}_2\text{O}}$. Therefore, if the urine is not hypo-osmotic, then the etiology is related to the kidney. Measuring the urinary sodium (U_{Na}) is a useful surrogate for urinary osmolality. Therefore a hypovolemic patient with an appropriately low U_{Na} (<20 mEq/L) has extrarenal sodium losses, such as from trauma, vomiting, diarrhea, burns, or third spacing. In a hypovolemic patient with an inappropriately high U_{Na} (>20 mEq/L), a renal source should be suspected, such as diuretic excess, osmotic diuresis, RTA, or mineralocorticoid deficiency. If the hyponatremic patient is hypervolemic, total body sodium can be low, normal, or high. A high U_{Na} that is greater than 20 mEq/L would point to renal failure. A low U_{Na} that is less than 20 mEq/L would suggest heart failure, cirrhosis, or nephrotic syndrome.

A patient who is euvolemic would exhibit low or normal total body sodium. The differential diagnosis would include glucocorticoid deficiency, hypothyroidism, stress, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). SIADH is a syndrome triggered by the release of ADH by a mechanism other than low blood volume or high plasma osmolality, one associated with increased aquaporin expression in the kidney (Kwon et al, 2001). The most common causes of SIADH are brain infections, surgery, neoplasm, and drug side effects (Box 44-2). Pharmacologic antagonists that can be used to treat patients with SIADH include lithium and demeclocycline. Lithium inhibits vasopressin action both proximal and distal to cAMP formation in the collecting duct (Miller, 1994). Demeclocycline, in doses ranging from 600 to 1200 mg/day, induces vasopressin-resistant diabetes insipidus that corrects the serum sodium within 1 to 2 weeks (Goh, 2004).

Therapy of hyponatremia is directed both at the cause of the condition and the water imbalance itself (Fig. 44-20). Patients with acute severe hyponatremia symptomatic with confusion, convulsions, or coma should undergo fluid restriction plus the administration of hypertonic (3%) saline (about 1 mL/kg/hr). Fluid overload is unlikely as long as fluid intake is restricted, but fluid may be further reduced by simultaneous administration of a loop diuretic such as furosemide, which causes excretion of hypotonic fluid equivalent to half-normal saline. The serum sodium concentration should be raised to no more than 25 mEq/L in the first 48 hours, at a rate of no more than 2 mEq/L per hour, and the target goal should be 120 to 125 mEq/L. Total sodium deficit to reach this point can be calculated as

$$(\text{Volume of distribution}) \times \text{body weight (kg)} \times (125 - \text{plasma [Na]})$$

where volume of distribution is 0.5 for men and 0.6 for women. If the hyponatremia is severe but chronic, the rate of correction should not exceed 8 to 12 mmol/L/day, otherwise a cerebral demyelination syndrome may occur (Martin, 2004). Therefore the rate of correction should be slower (0.5 to 1 mEq/L/hr). During acute intervention for severe hyponatremia, frequent electrolyte measurements and patient reassessment are required. Aggressive therapy should be discontinued when the serum sodium concentration is raised 10%

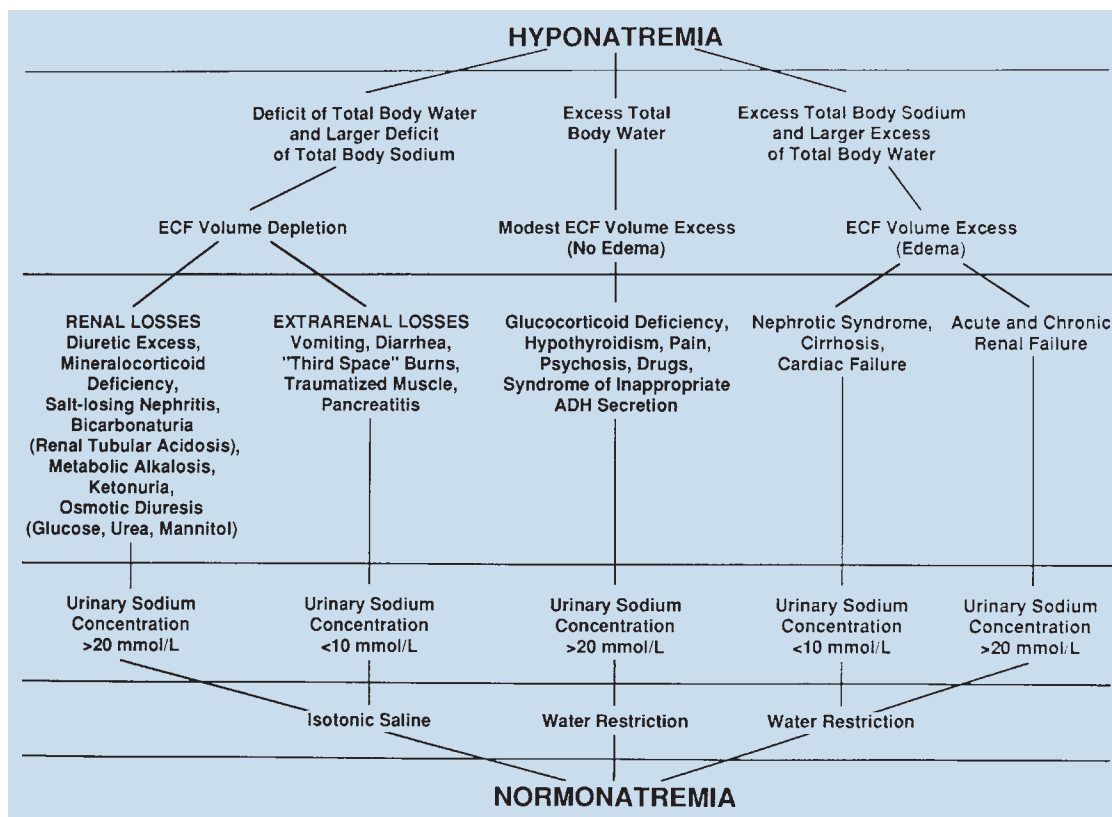

Figure 44-19. Clinical approach to patient with hyponatremia. ADH, antidiuretic hormone; ECF, extracellular fluid. (From Berl T, Anderson RJ, McDonald KM, Schrier RW. Clinical disorders of water metabolism. *Kidney Int* 1976;10:117–32.)

or symptoms subside. At that point, water restriction and reversal of underlying causes should suffice. This is also the best approach for therapy of asymptomatic hyponatremia. Obviously, patients with associated hypovolemia should have this corrected with the appropriate volume of normal saline.

Hypertatremia

The underlying problem of hypertatremia is a disorder of urine concentration with inadequate water intake (Adroque and Madias, 2000). Again, in hypertatremia it is the water balance that

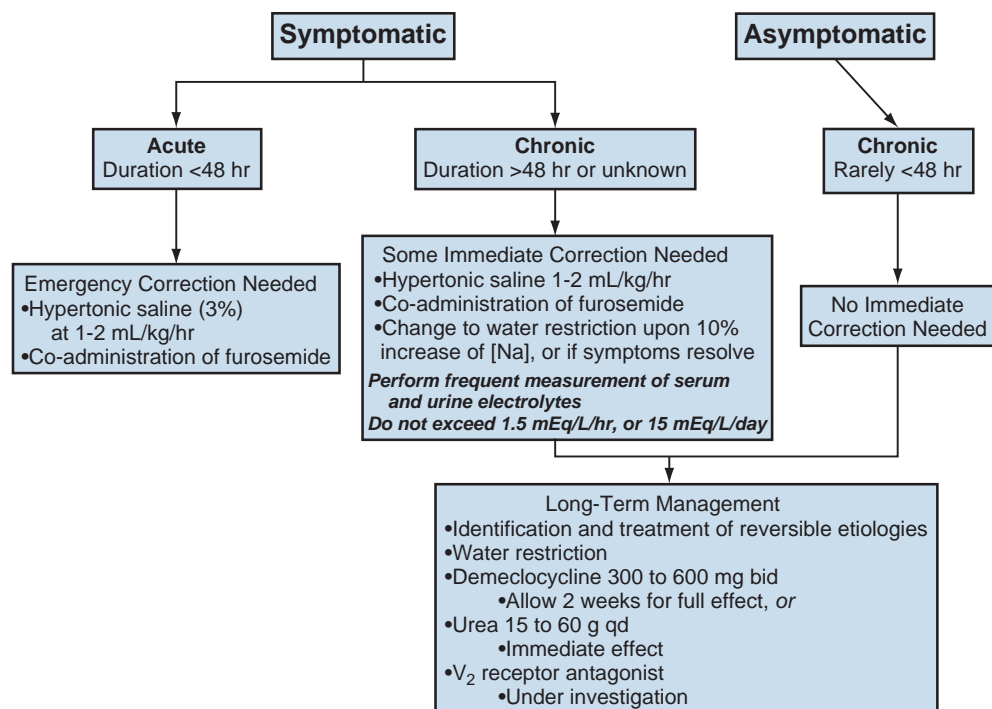

Figure 44-20. Therapy of hyponatremia. (From Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady H, Wilcox C, editors. Therapy in nephrology and hypertension. Philadelphia: Saunders; 1999. p. 261.)

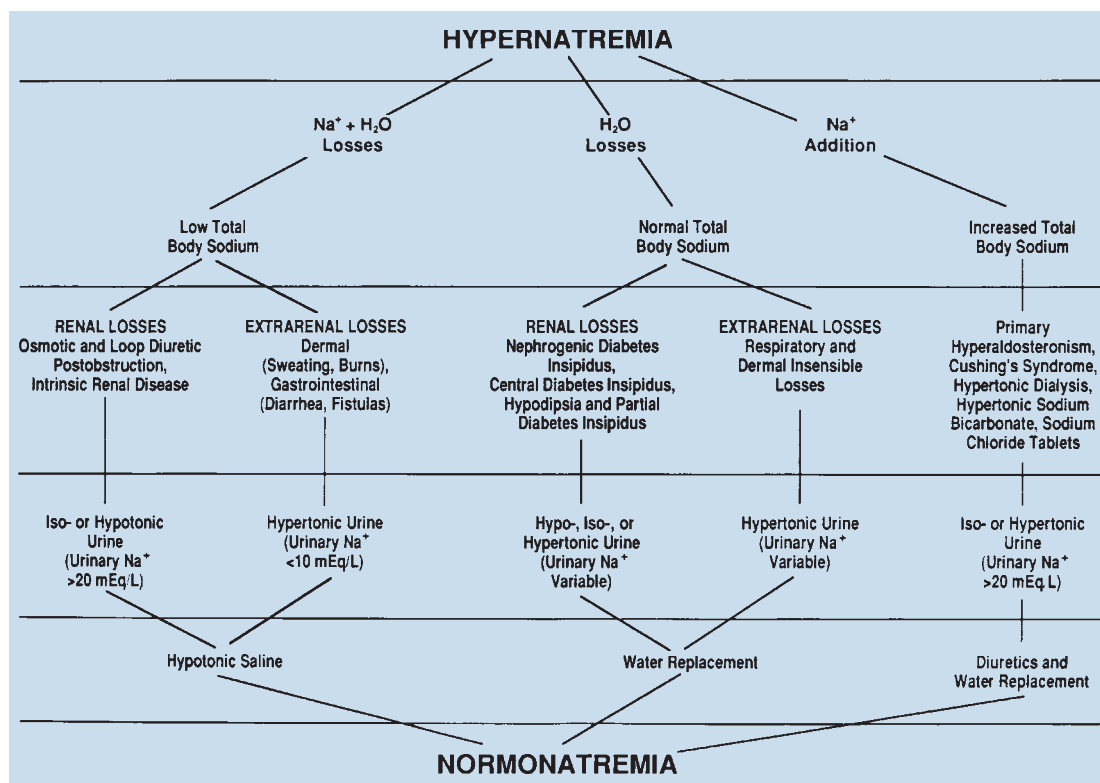

Figure 44-21. Clinical approach to patient with hypernatremia. (From Berl T, Anderson RJ, McDonald KM, Schrier RW. Clinical disorders of water metabolism. Kidney Int 1976;10:117–32.)

matters, and total body sodium can be high, normal, or even low. Symptoms are nonspecific and overlap with those seen in hyponatremia, with the early occurrence of restlessness, nausea, and vomiting, which can progress to tremor, lethargy, and coma. Indeed, mortality is higher with hypernatremia than with most

other electrolyte disorders. Most patients with an intact thirst mechanism and free access to water can prevent hypernatremia and, as such, the condition is more common at the extremes of age.

Again, the approach to a patient with hypernatremia begins with an assessment of fluid status (Fig. 44-21). Hypovolemia is

common and may be due to renal conditions that fail to adequately concentrate the urine (loop diuretics, postobstructive diuresis), or to conditions of extrarenal water loss, such as seen with burns, diarrhea, or fistulae. Patients with hypervolemia will have a metabolic or iatrogenic reason for high sodium in excess of the elevated total body water. Causes include Cushing syndrome, primary hyperaldosteronism, and excessive exogenous sodium (orally or IV). Patients who are euvoletic may have renal or extrarenal losses that may be caused by diabetes insipidus, an impairment in renal concentrating ability due to lack of central production (neurogenic), or impaired renal response (nephrogenic).

In neurogenic diabetes insipidus, vasopressin deficiency is most commonly caused by destruction of the neurohypophysis. To produce symptomatic polyuria, 80% to 90% of the neurosecretory neurons must be destroyed at or above the level of the infundibulum. Because of the reduced vasopressin level, the kidney excretes a high volume of dilute urine. This leads to a reduction in total body water, a rise in total body osmolality, and thus hypernatremia. The related cellular dehydration stimulates thirst. Compensatory water intake decreases plasma osmolality (and Na^+ concentration) toward normal, but they stabilize at the threshold level for thirst, which is slightly above normal. **As in all forms of diabetes insipidus, the ability of the kidney to maximally concentrate the urine in response to vasopressin is also impaired in neurogenic diabetes insipidus. This abnormality occurs because the medullary osmotic gradient is reduced by the high urine flow.** In nephrogenic diabetes insipidus, secretion of vasopressin by the neurohypophysis is normal, but renal responsiveness to the hormone is attenuated or absent, and urinary concentrating ability is impaired (Sasaki, 2004). Several different mutations of the aquaporin gene have been identified, which contribute to the pathogenesis of this disorder (Leung et al, 2005).

Therapy of hypernatremia is directed at fluid deficit, water replacement, and reversal of underlying causes. Hypovolemia should be initially corrected with half-normal saline. If the patient is awake and not symptomatic, oral hydration with water is sufficient. Otherwise, IV therapy should be started with the goal of slowly lowering plasma osmolality to no more than 2 mOsm/L/hr to avoid cerebral edema. The water deficit can be calculated as

$$(\text{Volume of distribution}) \times \text{body weight (kg)} \times (\text{plasma [Na]}/140 - 1)$$

where, again, volume of distribution is 0.5 for men and 0.6 for women. For patients with central diabetes insipidus, desmopressin (a synthetic exogenous vasopressin) can be administered intranasally. For nephrogenic diabetes insipidus, the underlying cause (lithium, hypercalcemia) should be treated. If polyuria persists while the kidney recovers, therapy includes modest sodium restriction, thiazide diuretics, and NSAIDs (Pattaragarn and Alon, 2003).

KEY POINTS: SODIUM AND WATER IMBALANCES

- Serum sodium represents sodium concentration and *not* total body sodium.
- The best tools to determine the cause of a sodium disorder are the history, volume status, and urinary sodium.
- Severe sodium deficit or excess must be corrected slowly.

Potassium Imbalances

Potassium is primarily an intracellular ion, and serum levels do not represent total body content in disease states. Because neuromuscular excitability is closely linked to serum potassium levels, extremes of low or high values can lead to cardiac arrhythmias and death. The body responds to changes in potassium intake and levels

by controlling urinary excretion and by changing the balance between intracellular and extracellular stores. **Urinary excretion can be increased in the kidney through increased aldosterone, a high sodium load in the distal tubule, and by acidosis. Potassium is driven into the cells by insulin, bicarbonate, and β agonists.**

Hypokalemia

The most common causes of hypokalemia are increased losses through the gastrointestinal (GI) tract or urine, and increased intracellular shift of potassium in response to alkalosis (mnemonic: aLKalosis = low K^+). The most common iatrogenic causes are diuretics, laxatives, amphotericin, theophylline, and postobstructive diuresis. Metabolic causes include conditions associated with elevated aldosterone, such as adrenal adenoma, Cushing syndrome, and adrenal carcinoma. The patient may have no symptoms or might present with signs and symptoms of his or her underlying condition (e.g., hypertension). Severe hypokalemia may produce tachycardia, heart block, and ST depression. Therapy is directed toward correction of the underlying cause and oral or parenteral potassium supplementation. In general, IV potassium replacement should not exceed 40 mEq/hr.

Hyperkalemia

Hyperkalemia usually reflects decreased renal excretion of potassium or a shift out of cells into the extracellular space (usually by acidosis). A compromised excretory capacity can be further exacerbated by a GI bleed or hemolysis. The most common causes of this condition (Box 44-3) are renal failure, drugs (potassium-sparing diuretics, lithium, digoxin, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs]), chronic acidosis (e.g., RTA type 4), and hypoaldosteronism. Hemolysis of the drawn blood sample can falsely elevate serum potassium. Therefore when a patient exhibits no symptoms, risk factors, or electrocardiogram (ECG) changes, but has an unexpectedly high value, the sample should be redrawn pending aggressive therapy. The classical ECG changes include a short QT interval, peaked T waves, and ultimately ventricular arrhythmias. Need for therapy is driven by the degree of elevation of potassium, the acuteness of elevation, and the presence of ECG changes. Mild hyperkalemia without ECG changes only requires dietary restriction and reversal of underlying causes. ECG changes require emergency therapy: IV calcium gluconate (to protect the heart) and a cocktail of drugs to drive the potassium into the cell, including sodium bicarbonate, insulin (administered with glucose to avoid hypoglycemia), and nebulized albuterol (especially if there is a delay in gaining IV access). Therapy to increase intracellular potassium must be coupled with a therapy to remove potassium stores, or the hyperkalemia will recur after infusions stop. Potassium-binding exchange resins (kayexalate, calcium resonium) can be used for this purpose orally or by enema. Finally, hemodialysis can most quickly and completely remove extracellular potassium.

KEY POINTS: POTASSIUM IMBALANCES

- Potassium is primarily intracellular.
- Serum potassium levels reflect total body potassium, as well as the equilibrium between intracellular and extracellular potassium.
- Alkalosis produces low serum potassium.

Acid-Base Metabolism

Although the hydrogen ion (H^+) is present in miniscule concentrations in the extracellular fluid, compared with other common

BOX 44-3 Etiology of Hyperkalemia**FACTITIOUS**

Laboratory error

Pseudohyperkalemia: in vitro hemolysis, thrombocytosis, leukocytosis

INCREASED INPUT

Exogenous: diet, salt substitutes

Endogenous: hemolysis, gastrointestinal bleeding, catabolic states, crush injury, tumor lysis

RENAL FAILURE

Acute: especially tubulointerstitial disease

Chronic: glomerular filtration rate <15 to 20 mL/min

IMPAIRED RENIN-ALDOSTERONE AXIS

Addison disease

Congenital adrenal enzyme deficiencies (e.g., corticosterone methyl oxidase deficiency)

Drug induced: heparin, prostaglandin inhibitors, angiotensin-converting enzyme inhibitors, pentamidine, β -blockers

Hyporeninemic hypoaldosteronism

Primary hypoaldosteronism (normal renin)

PRIMARY RENAL TUBULAR POTASSIUM SECRETORY DEFECT

Sickle cell disease

Systemic lupus erythematosus

Postrenal transplantation

Obstructive uropathy

Tubulointerstitial renal disease

Pseudohypoaldosteronism

Hyperkalemic distal renal tubular acidosis

INHIBITORS OF TUBULAR SECRETION

Diuretics: amiloride, spironolactone, triamterene

Cyclosporine

Lithium

Modified from Rastegar A, DeFronzo RA. Disorders of potassium metabolism associated with renal disease. In: Schrier RW, Gottschalk CW, editors. *Diseases of the kidney*. 5th ed. Boston: Little, Brown; 1992. p. 1645–2661.

ions in the body, its primary importance is reflected by the multiple mechanisms that exist to control its concentration within a tight range. The reason for this is that small alterations in H^+ concentration have large effects on the relative concentrations of every other conjugate base and acid of all the weak electrolytes. At neutral body pH, most biologically active molecules are in

their charged state and can be more effectively trapped within cells to perform their functions. Furthermore, pH determines the net charge of proteins, which influences protein conformation and enzyme-binding characteristics. Outside normal blood pH (7.35 to 7.46), severe metabolic problems occur.

To maintain pH, the body has to handle the daily production of acid. There is a large production of acid by the metabolism of carbohydrates and fats, largely in the form of carbon dioxide, at approximately 15,000 mmol per day. CO_2 is not an acid in the classical sense of the Brønsted-Lowry theory (Kildeberg, 1983), because it is not capable of donating a H^+ to a base. CO_2 can be considered a “volatile acid” because it is easily converted into H_2CO_3 , carbonic acid:

Each molecule of CO_2 excreted by the lungs is a result of the reaction of one molecule of bicarbonate with one molecule of H^+ . The H^+ remains in the body as H_2O . The catabolism of ingested proteins to amino acids is another source of acid production, estimated at between 50 and 100 mEq of H^+ per day (sulfate from the three sulfur-containing amino acids; phosphate from phosphoproteins). Because the lungs cannot excrete these acids, they are considered “fixed” and must be excreted by the kidneys.

Therefore the body has three primary mechanisms to handle physiologic and pathophysiologic acid loads: buffers in the blood, CO_2 excretion by the lungs, and H^+ excretion by HCO_3^- metabolism in the kidneys (Vasuvattakul et al, 1992). The immediate response to an acid load is buffering. A buffer is simply a mixture of a weak acid and its conjugate base, or a weak base and its conjugate acid, that resists changes in pH when another acid or base is added. The key buffers in the blood are HCO_3^- for metabolic acids and hemoglobin for CO_2 . Within the cell, proteins and phosphates, which are found in higher concentrations than in the blood, become important as well. In the extracellular fluid, HCO_3^- is responsible for about 80% of buffering. Changes in pH are governed by the Henderson-Hasselbalch equation, which generally is

$$pH = pK_a + \log \text{base/acid}$$

When specifically formulated for the bicarbonate system it becomes

$$pH = 6.1 + \log HCO_3^- / 0.03 \times pCO_2$$

In general, optimal buffering occurs within 1.0 pH unit of the pK_a . Therefore the $pK_a = 6.1$ of bicarbonate buffer does not appear to be the most efficient for maintaining the pH 7.4 that is required for normal homeostasis. **The bicarbonate buffer system is effective despite having a low pK_a , because the body also controls pCO_2 .**

Excretion of CO_2 by the lungs can occur rapidly and can change both blood and intracellular pH. Elevated pCO_2 is detected by central and peripheral chemoreceptors that increase respiratory rate leading to increased alveolar ventilation. Respiratory compensation in response to a pure metabolic acidosis cannot reduce CO_2 to below 10 mm Hg and is therefore unable to maintain pH in the setting of a large acid load.

Although most of the daily acid production is volatile, and is therefore excreted by the lungs, the kidneys must excrete the fixed acid, and in doing so must also reabsorb most of the filtered bicarbonate so that efficient extracellular buffering can be maintained. A normal individual, with a GFR of 180 L/day and plasma $[HCO_3^-]$ of 24 mEq/L, filters 4300 mEq of HCO_3^- daily from the glomerulus into the proximal tubule. Of this filtered load, less than 0.1% normally appears in the urine. **The bulk of the filtered bicarbonate is reclaimed in the proximal nephron, with approximately 80% of the filtered HCO_3^- reabsorbed within the PCT.** In the tubular urine, H^+ and HCO_3^- are formed from CO_2 and H_2O in a reaction catalyzed by carbonic anhydrase (Kaunisto et al, 2002). The H^+ is returned to the tubular urine by two mechanisms: a Na^+-H^+ pump (“antiporter”) and a direct $H^+-ATPase$ proton pump. The net result

is the reabsorption of NaHCO_3 into the interstitial fluid and the secretion of H^+ into the proximal collecting duct urine. Note that the use of a carbonic anhydrase inhibitor, such as acetazolamide, reduces HCO_3^- reabsorption and increases excretion of Na^+ and water, resulting in a weak diuretic effect (Puscas et al, 1999). The reabsorption of HCO_3^- does not result in a net excretion of H^+ from the body; however, the proximal tubular reabsorption of HCO_3^- is essential to preserving acid-base balance. The primary factors that increase HCO_3^- reabsorption are arterial pCO_2 , HCO_3^- concentration in the lumen, luminal flow rate, and angiotensin II (de Mello-Aires and Malnic, 2002).

The remainder of the filtered bicarbonate is reabsorbed in the distal nephron by a mechanism independent of carbonic anhydrase. In the distal tubule, further H^+ is secreted through the production of "titratable acid," usually by buffering with phosphate. The term *titratable acidity* refers to the quantity of NaOH required to titrate urine back to a pH of 7.40, which is similar to that of blood. Other buffers, such as uric acid (pK_a 5.75) and creatinine (pK_a 4.97) contribute to the titratable acidity, but only to a minor extent. H^+ is also secreted through the production of ammonium ion (NH_4^+). NH_4 is produced from glutamine, primarily by proximal tubular cells (Michoudet et al, 1994). Because of its high pK_a (about 9.2), it is present almost exclusively as the NH_4^+ ion. Ammonium excretion can increase significantly during systemic acidosis (Nagami, 2004), which is the key mechanism for secreting excess H^+ , because at very low urinary pH, titratable acid cannot increase much (unless other ions, such as keto-anions, are being produced).

Regulation of H^+ secretion occurs through multiple biochemical and hormonal actions on the aforementioned system. **Volume depletion** leads to Na retention and enhanced HCO_3^- absorption, with a net loss of H^+ . **Elevated pCO_2** , as seen in chronic respiratory acidosis (see later), will lead to a renal response of increased H^+ secretion. **Reduced GFR** will reduce the amount of filtered HCO_3^- , leading to increased H^+ excretion. **High aldosterone levels** indirectly increase H^+ excretion by increasing Na^+ absorption. **Low potassium and low chloride** increase HCO_3^- reabsorption and can maintain chronic metabolic alkalosis.

Acid-Base Disorders

Those of us outside the fields of nephrology and anesthesia encounter acid-base disorders less commonly and are often intimidated by the process of working through the appropriate diagnosis. Nevertheless, after the terminology and basic equations are understood, the process is simple and, in many ways, mechanical (Corey, 2005). Common misconceptions begin with definitions of terms. **The actual pH disturbance is an "emia," and the disease causing it is an "osis."** Acidemia refers strictly to a low arterial blood pH of less than 7.36. **Alkalemia** is a blood pH of greater than 7.44. **Acidosis** is an abnormal condition or process that would lower arterial pH if no other condition existed, and **alkalosis** is a condition that would raise pH. **The basic information required to diagnose an acid-base disturbance is a history, physical examination, serum electrolytes, and arterial blood gas.** If the acid-base disorder is caused by a respiratory problem, the pCO_2 will move in a direction opposite to the pH (Madias and Adrogué, 2003). If caused by a metabolic (renal) disorder, the HCO_3^- will move in the same direction as the pH. In every disorder, there should be an attempt by the other acid-handling mechanism to compensate for the change. For instance, chronic loss of bicarbonate from the kidney causing a metabolic acidosis (low pH and low HCO_3^-) should lead to increased ventilation to try to excrete the excess acid by the lung, leading to a lower pCO_2 (respiratory compensation). In **simple** acid-base disorders, there is one mechanism causing the acid disturbance with an appropriate compensation. In **mixed** disorders, the clue to multiple mechanisms comes from significant undercompensation or overcompensation. Although formulas have been developed to predict appropriate compensation for each disorder, visual nomograms are more practically used at the bedside.

Metabolic Acidosis

In metabolic acidosis, loss of bicarbonate leads to systemic acidemia, which produces a low arterial pH and low serum HCO_3^- . The appropriate compensation is increased respiration leading to a reduced pCO_2 . In general, the expected degree of pCO_2 reduction is calculated as

$$\text{Expected } \text{pCO}_2 = 1.5 \times [\text{HCO}_3^-] + 8 \pm 2$$

This bicarbonate loss can be direct, or it can result from secondary effects of other ions. The presence of active ions that are not measured in routine blood chemistry can be detected by the anion gap. The anion gap is defined as the difference between the levels of routinely measured cations (Na^+) and anions (Cl^- and CO_2) in blood:

$$\text{Anion gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = 140 - (105 + 24) = 11$$

The normal range of the anion gap is 9 to 14 mEq/L. The predominant unmeasured anions include albumin and phosphate. The major unmeasured cations include calcium, magnesium, and gamma globulins. If the anion gap is elevated in a patient with metabolic acidosis, the condition occurs because acids that do not contain chloride are present in the blood. The most common of these are ketones (diabetic ketoacidosis), lactate (lactic acidosis), and drug intoxication (methanol, aspirin) (Levrault and Grimaud, 2003).

Metabolic acidosis with a normal anion gap is caused by direct bicarbonate loss through the gut or kidney, or by the addition of exogenous acid that is buffered by bicarbonate (Box 44-4). The patient history can provide major clues to the diagnosis, either because of GI loss (vomiting, diarrhea, fistula), drug use (acetazolamide), or previous surgery (ileal conduit). Serum potassium can be a further clue to etiology. Low potassium is associated with loss through the GI tract or RTA because renin is stimulated from the volume contraction. In acidosis

BOX 44-4 Hyperchloremic Metabolic Acidosis (Normal Anion Gap)

Acid loads

- Ammonium chloride
- Hyperalimentation
- Ketoacidosis with renal ketone loss

Bicarbonate losses

- Diarrhea
- Pancreatic, biliary, or small bowel drainage
- Ureterosigmoidostomy

Drugs

- Cholestyramine
- Calcium chloride
- Magnesium sulfate
- Posthypocapnia

Defects in renal acidification

- Proximal: decreased HCO_3^- reclamation
- Distal: decreased net acid excretion
 - Primary mineralocorticoid deficiency
 - Hyper-reninemic hypoaldosteronism
 - Mineralocorticoid-resistant hyperkalemia

Dilutional

associated with severe renal dysfunction, potassium will often be elevated.

Renal Tubular Acidosis

RTA is a family of syndromes of metabolic acidosis from defects in tubular H⁺ secretion and urinary acidification. They are classified according to the mechanism of defect, and each type includes different clinical manifestations.

RTA type 1 is the most common form and is the most clinically significant to the urologist. It has also been called “classic” RTA and distal RTA. The old classification of RTA type 3 is now recognized as a type 1 variant. The underlying problem is failure of H⁺ secretion in the distal nephron, which can be congenital or acquired. Associated disorders include autoimmune diseases (thyroiditis), toxic nephropathy, and chronic ureteral obstruction. The hallmark is a hyperchloremic metabolic acidosis with a high urinary pH (>5.5) in the face of persistently low serum HCO₃⁻. If no metabolic acidosis is present but the condition is still suspected, then acid loading with ammonium chloride will drop the serum HCO₃⁻ while maintaining a high urine pH. Volume contraction from sodium loss is common, which leads to secondary hyperaldosteronism and hypokalemia. These patients often develop recurrent renal stones that are composed of calcium phosphate. The most likely contributing factor is low urinary citrate, coupled with a high urinary pH and hypercalciuria. Treatment with sodium bicarbonate can alkalinize the urine, correct the sodium defect, lower aldosterone, and raise the potassium. Potassium citrate can augment the urinary citrate levels and can inhibit stone formation (Domrongkitchaiporn et al, 2002).

Type 2 RTA, also called proximal, is caused by failure of bicarbonate reabsorption in the proximal tubule (Igarashi et al, 2002). The mechanisms of H⁺ secretion in the distal tubular are overwhelmed, resulting in HCO₃⁻ loss in the urine. Cl⁻ resulting in hyperchloremia is replaced in the circulation by bicarbonate. Increased sodium delivery to the distal tubule increases aldosterone secretion resulting in hypokalemia. Ultimately, a new steady state is reached, in which serum HCO₃⁻ is decreased, and hence the filtered load, distal delivery, and urinary excretion of HCO₃⁻ are all reduced. The acidosis is self-limited, because acid production and excretion are equivalent at this reduced pH; the plasma HCO₃⁻ remains at 15 to 20 mEq/L. Because urinary citrate levels are not reduced, stone formation does not occur, despite increased urinary calcium. Because this condition is more common in children, it can lead to growth retardation and metabolic bone disease (Roth and Chan, 2001). Oral supplementation with NaHCO₃ can correct the condition but can lead to further hypokalemia, so potassium supplements may also be required. As an interesting aside (and possible memory aid), it was suggested that Dickens’ Tiny Tim character was based on a child with type 2 RTA (growth retardation, osteomalacia) that was reversed when Mr. Scrooge paid for his therapy (sodium bicarbonate).

Type 4 RTA is a result of impairment of cation exchange in the distal tubule, with reduced secretion of both H⁺ and K⁺. It is due to

aldosterone deficiency or resistance. The unique feature compared with other RTAs is hyperkalemia. Patients often have associated azotemia and hypertension. The distal tubule H⁺ pump functions normally, so patients are able to decrease urine pH to less than 5.5 in response to the acidosis. Urinary citrate may be normal or low, but renal dysfunction reduces secretion of calcium and uric acid, so stones do not form (Uribarri et al, 1994). Type 4 RTA is occasionally seen in obstructive uropathy. Therapy is typically directed at controlling the hyperkalemia.

Metabolic Alkalosis

In metabolic alkalosis, the pH will be high (alkalemia) and the HCO₃⁻ high (mirrors pH in primary metabolic disorder) (Khanna and Kurtzman, 2001). The appropriate respiratory compensation is reduced ventilation with increased pCO₂. The expected degree of respiratory compensation can be estimated by

Expected pCO₂ = 6 mm Hg per 10 mEq/L increase in HCO₃⁻

An exogenous alkali load is usually rapidly excreted into the urine by the kidney, so other mechanisms are required to maintain the disorder. Maintenance of the alkalosis requires a process that greatly impairs the kidney’s ability to excrete bicarbonate and prevent the return of the elevated plasma level to normal. Chloride deficiency leads to the kidney reabsorbing more bicarbonate anion than usual because there is not sufficient chloride anion present to maintain electroneutrality. This condition is reversed with fluid and chloride. Consequently, metabolic alkalosis is most conveniently classified as chloride responsive and chloride resistant.

The most common chloride-responsive conditions are GI loss (vomiting, nasogastric drainage, laxative abuse) and kidney loss (diuretics). These make up more than 90% of clinical cases of metabolic alkalosis (Table 44-2). Volume contraction in these conditions stimulates aldosterone production and distal secretion of H⁺ and K⁺. Thus there may be a paradoxical aciduria that will persist until volume is replaced. Chloride-resistant metabolic alkalosis is associated with potassium loss from mineralocorticoid excess. The disorders are associated with volume expansion and high urinary chloride levels, which can aid in the diagnosis. Common causes are hyperaldosteronism (primary or secondary), Cushing syndrome, diuretics, and congenital conditions such as Bartter syndrome (hyperplasia of the juxtaglomerular apparatus).

Respiratory Acidosis

In respiratory acidosis, pH is low (acidemia) and pCO₂ is high because of inadequate respiration (Epstein and Singh, 2001). The anticipated compensatory response is increased HCO₃⁻:

Acute: Expected HCO₃⁻ = 1 mEq/L for each 10 mmHg pCO₂

Chronic: Expected HCO₃⁻ = 3.5 mEq/L for each 10 mmHg pCO₂

Elevated pCO₂ can be caused by increased production of CO₂, decreased ventilation, and increased CO₂ in the inspired air.

TABLE 44-2 Differential Diagnosis of Metabolic Alkalosis

MEASUREMENT	SALINE RESPONSIVE	NORMOTENSIVE: SALINE UNRESPONSIVE	HYPERTENSIVE: SALINE UNRESPONSIVE
Urinary [Cl ⁻]	<15 mEq/L	>15 mEq/L	>15 mEq/L
Blood pressure	Normal	Normal	Increased
Differential diagnosis	Vomiting Nasogastric suction	Diuretics Bartter magnesium deficiency	Primary mineralocorticoid excess

Modified from Alpern RJ, Emmett M, Seldin DW. Metabolic alkalosis. In: Seldin DW, Giebisch G, editors. The kidney: physiology and pathophysiology. 2nd ed. New York: Raven; 1992. p. 2733–58.

Because increased production is usually handled quickly by increased respiration, and CO_2 does not vary except in ventilated patients, the most common cause is decreased ventilation. This can be a result of central depression of respiration (e.g., opiates, trauma, cervical cord trauma), chest cavity problems (e.g., pneumothorax, pulmonary edema), upper airway obstruction, or iatrogenic causes (insufficient ventilation). Because CO_2 readily diffuses across all cellular membranes, marked elevation can severely interfere with intracellular metabolism. Clinical effects of elevated pCO_2 , which are separate from acidosis per se, include elevated intracranial pressure, tachycardia, central depression, and eventually coma and death.

Respiratory Alkalosis

In respiratory alkalosis, pH is high (alkalemia) because of a low pCO_2 . This is due to hyperventilation (Foster et al, 2001). The appropriate compensatory response is a lowering of HCO_3^- by the following expected amounts:

Acute: Expected $\text{HCO}_3^- = 2 \text{ mEq/L}$ for each 10 mmHg pCO_2

Chronic: Expected $\text{HCO}_3^- = 5 \text{ mEq/L}$ for each 10 mmHg pCO_2

Common causes of hyperventilation that can lead to respiratory alkalosis are fever, pain, anxiety, septicemia, head trauma, pulmonary embolism, and iatrogenic causes (excessive mechanical ventilation). Neurologic symptoms such as paresthesia and tetany may occur. Therapy is directed toward improving oxygenation and ventilation.

KEY POINTS: ACID-BASE METABOLISM/DISORDERS

- Physiologic chemical reactions require a narrow range of serum pH.
- Acid is excreted through the lungs and the kidney.
- Type 1 RTA (distal) is the only type associated with renal stones.
- In acid-base disorders, first determine whether the kidney (HCO_3^-) or lungs (pCO_2) are responsible for the primary disorder; then determine whether the compensatory response is appropriate.

Pathophysiology of Ischemic Nephropathy

Screening Tests

Pathology of Renovascular Hypertension

Physiologic Significance

Management of Renovascular Hypertension

Partial or complete occlusion of one or both renal arteries may result in renal ischemia and as a consequence may result in “renovascular” hypertension, the most common form of secondary and potentially curable hypertension (Spitalewitz and Reiser, 2000; Safian and Textor, 2001). Furthermore, a substantial number of affected patients may develop ischemic nephropathy and ultimately progress to end-stage renal disease (ESRD) (Plath, 1995; Ram et al, 1995; Spitalewitz and Reiser, 2000; Safian and Textor, 2001). Although affecting only 5% of hypertensives, renal artery disease has been estimated to be the cause of renal failure in 5% to 15% of those older than 50 years of age and may account for as many as 10% to 20% of the ESRD population (Jacobson, 1988; Rimmer and Gennari, 1993; Mailloux et al, 1994; Greco and Breyer, 1997; Middleton, 1998; van Ampting et al, 2003). As a result, renovascular disease poses a major health problem and its therapy remains a challenge for physicians caring for these patients.

INCIDENCE AND ETIOLOGY

Most patients with renovascular hypertension present with moderate to severe hypertension, with only a small percentage presenting with mild hypertension or presenting as normotensive. In 10% to 45% of the cases, renovascular disease may lead to accelerated or malignant hypertension (Davis et al, 1979; Svetkey et al, 1991). Although the diagnosis of renovascular hypertension is more commonly made in Caucasians than African-Americans, the finding of a similar prevalence in both racial groups in one carefully conducted study suggests that this difference may in part be a result of racial bias in performing diagnostic studies (Svetkey et al, 1991).

The most common forms of renovascular hypertension are due to atherosclerotic disease and fibromuscular dysplasia, with the former accounting for more than two thirds of the cases. Atherosclerotic renal artery disease is most frequently seen in those older than 40 years of age, is more often seen in men than women, and generally involves the ostium and/or proximal third of the renal artery (Wollenweber et al, 1968; Plath, 1995). Fibromuscular disease is more often seen in younger Caucasian women, is usually bilateral, and unlike atherosclerotic disease it involves the more distal segments of the renal arteries (Pohl, 1993).

The following signs and symptoms should raise suspicion of the possibility of underlying renovascular disease and the need for further evaluation if warranted:

1. Severe or refractory hypertension with evidence of grade III or IV hypertensive retinopathy (particularly in Caucasians)
2. Abrupt onset of moderate to severe hypertension, particularly in a normotensive or previously well-controlled hypertensive

3. Onset of hypertension before age 20 (early onset) or after age 50 (late onset), particularly in those without a family history of hypertension
4. Unexplained worsening of renal function with or without hypertension or in association with the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) or with a reduction of blood pressure (BP) to the current accepted norm with the use of other antihypertensive agents
5. Paradoxical worsening of hypertension with the use of diuretics
6. Unexplained recurrent episodes of heart failure—“flash” pulmonary edema
7. The presence of a systolic-diastolic abdominal bruit that radiates to both flanks
8. The presence of diffuse vascular disease and/or evidence of cholesterol embolization (Rose, 1987; Plath, 1995)

Because effective BP control may be achieved in most patients with renovascular hypertension, and it remains uncertain whether the correction of an underlying vascular lesion results in long-term BP control or preservation of renal function, testing for renovascular hypertension should be pursued only if revascularization is being seriously considered. Some screening techniques (see later) pose risks to those with compromised renal function and may be associated with significant morbidity (White et al, 2006).

KEY POINTS: INCIDENCE AND ETIOLOGY

- Although renal artery disease affects only a small proportion of hypertensives, it may be the cause of renal failure in as many as 10% to 20% of patients with ESRD. Therefore renal vascular disease is a major health problem and its therapy remains a significant challenge.
- Most patients with renal vascular hypertension present with moderate to severe hypertension.
- This disease appears similarly prevalent in Caucasians and African-Americans.
- The most common form of renal vascular hypertension is atherosclerotic involvement of the renal arteries.
- It remains uncertain whether the correction of an underlying vascular lesion results in long-term BP control or preservation of renal function.

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

In 1934, Goldblatt and colleagues performed the now classic experiment on dogs to test the hypothesis of whether or not renal ischemia is the inciting event in the pathogenesis of hypertensive

nephrosclerosis (Goldblatt et al, 1934). With the use of a clamp that allowed them to control the degree of renal artery stenosis (RAS), Goldblatt was able to monitor the BP in the dogs after clamping the renal artery to one or both kidneys and to one kidney after the removal of the contralateral kidney. Because BP remained elevated in all three models, this study confirmed the hypothesis, “renal ischemia in dogs is a sufficient condition for the production of persistently elevated systolic blood pressure.” However, the mechanism by which the hypertension was induced remained to be elucidated.

Subsequently, two animal models of renal hypertension have become the hallmark for all studies on experimental renovascular hypertension. They are (1) the two-kidney hypertension model, where one renal artery is clipped and the other renal artery is left unaltered (2K1C), and (2) the one-kidney hypertension model, where one renal artery is clipped and the contralateral kidney is removed (1K1C).

These two models have clarified the vasoconstriction-volume interactions that regulate renal hypertension.

Two-Kidney, One-Clip Model

The two-kidney, one-clip model is the one most similar to human renovascular hypertension. Because of the ischemia induced by the stenosis, renin secretion is increased from the juxtaglomerular apparatus of the ischemic kidney and suppressed in the normal contralateral kidney. As a consequence of the activation of the renin-angiotensin-aldosterone system (RAAS) and an increased production of angiotensin II (AII), there is peripheral vasoconstriction and hypertension (Vaughan and Laragh, 1975). The key finding is that the hypertension that ensues is mediated by a vasoconstrictor, AII, and is therefore referred to as the **vasoconstrictor hypertensive model** (Fig. 45-1) (Vaughan and Laragh, 1975). AII stimulates aldosterone secretion and in turn sodium retention. However, the normal contralateral kidney with its renin secretion suppressed and under a higher perfusion pressure is able to excrete

most of the excess salt and water. Because there is limited sodium retention, there is no significant feedback inhibition of renin secretion in the stenotic kidney. Thus it continues to secrete AII and the vasoconstriction and hypertension is maintained. The renin dependency of hypertension in the 2K1C model has been further supported by studies using inhibitors or blockers of the RAAS such as AII antagonists (Bumpus et al, 1976; Caravaggi et al, 1976), renin antibodies (Romero et al, 1973), and ACE inhibitors (Romero et al, 1974).

This form of hypertension may be managed with reversal of the RAS (or unclipping of the “clipped kidney”), with ACE inhibition, or with angiotensin receptor blockade.

One-Kidney, One-Clip Model

In the 1K1C model there is activation of the RAAS similar to that seen in the 2K1C model. However, in contrast to the 2K1C kidney, the absence of a normal contralateral kidney prevents an ensuing natriuresis and diuresis. Thus there is volume expansion, and renin secretion is suppressed in the clipped kidney because of feedback inhibition. Volume expansion remains, and there is sustained hypertension in spite of the decreased vasoconstriction associated with the now suppressed RAAS. Despite the similarity in the initiating events in both experimental models of renal hypertension, the 1K1C model is driven by volume expansion and sodium retention with normal circulating levels of AII. This is therefore called the **volume hypertensive model** (Fig. 45-2) (Vaughan and Laragh, 1975).

PATHOPHYSIOLOGY OF ISCHEMIC NEPHROPATHY

In addition to hypertension, RAS, when hemodynamically significant, affects the entire renal functioning parenchyma and causes ischemic nephropathy, which is defined as a decrease in the glomerular filtration rate (GFR) with several histologic changes that

Figure 45-1. The renin system in the setting of unilateral renal artery stenosis with a normal contralateral kidney characterized by (1) high peripheral plasma renin activity, (2) contralateral suppression of renin release, and (3) a decrease in ipsilateral renal blood flow (RBF). The resultant hypertension is mediated by angiotensin II induced vasoconstriction. (From Vaughan E, Laragh J. New concepts of the renin system and vasoconstriction-volume mechanisms: diagnosis and treatment of renovascular and renal hypertension. *Urol Clin North Am* 1975;2:240–1, figure 2.)

direct stimulation of proinflammatory cytokines. In addition, RAS leads to the production of AII, which is a powerful vasoconstrictor, but in this context it is more important that AII is a profibrogenic peptide. AII has been shown to increase the production of transforming growth factor- β (TGF- β) by various cells including renal tubular cells and fibroblasts (Klahr and Morrissey, 2002). TGF- β activation stimulates fibrosis through the production of inhibitors of matrix-degrading enzymes, the transformation of fibroblasts into myofibroblasts, and the transdifferentiation of tubular epithelial cells into myofibroblasts (Eddy, 2000). AII also stimulates the production of nuclear factor- κ B (NF- κ B), a family of transcription factors that is central to controlling two autocrine-reinforcing loops that continue to amplify the production of AII and tumor necrosis factor- α (TNF- α) (Fig. 45-4) (Klahr and Morrissey, 2002). The oxidative stress of RAS fueled by AII also increases the production of adhesion molecules, chemoattractant compounds, and cytokines, further stimulating the fibrotic process (Klahr and Morrissey, 2002). These processes result in tubulointerstitial inflammation, the accumulation of extracellular proteins within the interstitial space, peritubular capillary obliteration, tubular atrophy, renal fibrosis, and ultimately loss of renal function. The previous hypotheses are supported by the fact that the administration of AII receptor antagonists or ACE inhibitors in experimental renal disease models have both been shown to reduce the production of TGF- β and to mitigate renal interstitial fibrosis (Ishidoya et al, 1995; Pimentel et al, 1995).

In summary, although the initiating event in RAS is a decrease in RBF and a measurable increase in a powerful vasoconstrictor (AII), it is likely other molecular and fibrogenic effects of this peptide are more damaging to the renal parenchyma than the decrement of RBF and the elevation in BP.

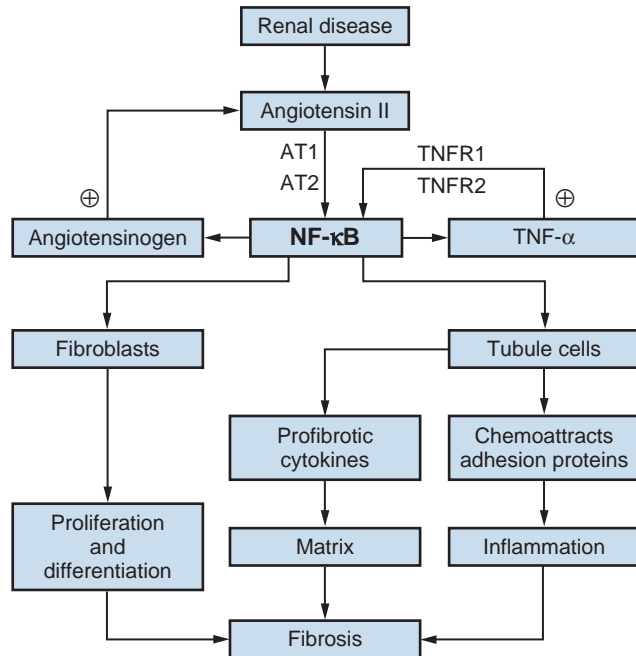

Figure 45-4. The regulation of gene expression by angiotensin II occurs through specific receptors that are ultimately linked to changes in the activity of transcription factors within the nucleus of target cells. In particular, members of the nuclear factor- κ B (NF- κ B) family of transcription factors are activated, which, in turn, fuels at least two autocrine reinforcing loops that amplify angiotensin II and tumor necrosis factor (TNF) formation. TNFR1 and TNFR2, TNF receptors. (From Novick A, Fergany A. Pathophysiology of ischemic nephropathy. In: Walsh PC, Retik AB, Vaughan ED Jr, et al, editors. *Campbell's Urology*. 8th ed. Philadelphia: Saunders; 2002. p. 239.)

KEY POINTS: PATHOPHYSIOLOGY OF ISCHEMIC NEPHROPATHY

- A stenosis of at least 70% to 80% is considered to be hemodynamically significant.
- It is unlikely that the renal damage observed in RAS is secondary to the decrement in RBF alone.
- Multiple molecular and fibrogenic factors contribute to the damage of the renal parenchyma observed after there is a decrement in RBF and an elevation in BP.

SCREENING TESTS

Several noninvasive screening tests are used for diagnosing renovascular disease. Both intravenous pyelography (IVP) and plasma renin activity were used in the past, but they have been replaced by more sensitive and specific techniques. Although renal scintigraphy with ACE inhibition is easy to perform, does not require the discontinuation of antihypertensive medications (except for ACE inhibitors and ARBs at least 48 hours before the study), and may predict the BP response to intervention, its use as an initial screening test has been questioned because of the variability of its sensitivity and its specificity in different studies. In addition, the finding of asymmetric RBF in those with moderate to severe hypertension in the absence of renovascular disease, and the test's poor diagnostic accuracy in those with advanced renal failure (particularly those with creatinine clearances <20 mL/min) or bilateral disease, further limit its utility (Setaro et al, 1991; Mann and Pickering, 1992; Pedersen, 1994; van Jaarsveld et al, 1997; van Onna et al, 2003; Krijnen et al, 2004). As a result, renal scintigraphy is no longer recommended as a screening test to establish the diagnosis of RAS. The screening tests that provide the highest sensitivity and specificity are magnetic resonance angiography (MRA), spiral (helical) computed tomography (CT), and duplex Doppler ultrasonography.

KEY POINTS: SCREENING TESTS

- Renal scintigraphy is no longer recommended as a screening test to establish the diagnosis of RAS.
- The screening tests that provide a higher sensitivity and specificity are MRA, spiral CT, and duplex Doppler ultrasonography.

Magnetic Resonance Angiography

MRA with gadolinium provides a sensitive noninvasive screening test for detecting renovascular disease. In addition to visualizing the renal artery, it can provide an assessment of the functional significance of the renovascular lesion, because both the RBF and the GFR can be determined by the study. Two prospective studies compared MRA with digital subtraction angiography (DSA) or renal angiography and demonstrated that MRA had a sensitivity of 100% for detecting a renovascular lesion of the main renal artery and a specificity of 71% to 96% (Postma et al, 1997; Rieumont et al, 1997). Three-dimensional MRA when combined with cardiac synchronization can visualize the entire length of the major renal arteries. However, lesions involving the distal, intrarenal, and accessory arteries, which may be of hemodynamic significance, may be missed because of poor visualization (Sommer et al, 1992; Klatzburg et al, 1994; de Haan et al, 1996; Schoenberg et al, 1998). Although initially thought to be safe in those with underlying renal insufficiency, concerns regarding the possibility of gadolinium-induced nephrogenic systemic fibrosis have diminished its utility in those with unstable or reduced

renal function (GFR <30 mL/min). In these patients, a noncontrast MRA study may be performed, but this shows far less sensitivity and positive predictive value than a gadolinium-enhanced study (Tan et al, 2002).

Computed Tomography

Spiral (helical) CT angiography with intravenous radiocontrast has shown in some studies a sensitivity of 98% and a specificity of 94% for detecting renovascular lesions (Olbricht et al, 1995). When compared with intra-arterial DSA in potential renal donors with normal renal function suspected of having underlying renovascular disease, CT angiography identified all lesions of the main renal artery greater than 50% and 27 of 28 accessory arteries (Kim et al, 1998). Because both the sensitivity and specificity of CT angiography decline (93% and 81%, respectively) in the presence of renal insufficiency (serum creatinine >1.7 mg/dL, and the risk of dye-induced nephrotoxicity increases, the usefulness of this screening technique is limited in those with renal insufficiency.

Duplex Doppler Ultrasonography

Similar to MRA, duplex Doppler ultrasonography provides both anatomic and functional information. Via B-mode ultrasonography, the main renal arteries may be visualized, and when combined with Doppler measurements of various hemodynamic parameters, particularly peak systolic velocity, one can accurately identify renal artery lesions (Hoffman et al, 1991; Klierer et al, 1994; Stavros and Harshfield 1994; Olin et al, 1995; Marana et al, 1998; Williams et al, 2007). The sensitivity of this technique may be further increased when ACE inhibition is used to enhance the waveforms distal to the arterial lesion (Rene et al, 1995). When the resistive index $[1 - (\text{end diastolic velocity} \div \text{peak systolic velocity})] \times 100$ is calculated during duplex Doppler scanning, a measure of the structural alterations in the smaller distal renal arteries and arterioles is obtained and may help predict the patients who will have an improvement in their BP and/or renal function following revascularization of their lesion(s) (Stavros and Harshfield, 1994; Kaplan-Pavlovic and Nadja, 1998; Marana et al, 1998; Radermacher et al, 2001). However, the accuracy is not sufficient to allow this parameter alone to determine whether one should or should not proceed with revascularization (Zeller et al, 2003; Crutchley et al, 2009).

As a screening test, duplex Doppler ultrasonography provides many advantages. It can demonstrate bilateral disease, does not require the discontinuation of antihypertensive therapy or the exposure to potentially nephrotoxic contrast, and is accurate for those with renal failure. Despite these advantages, the use of duplex Doppler ultrasonography is limited by the fact that it is time consuming, is highly operator dependent, and is a technically difficult test to perform. Further, intrarenal vascular lesions and multiple (and even main) renal arteries might not be adequately visualized in obese patients and in those with overlying intestinal gas (Hoffman et al, 1991; Olin et al, 1995; Kaplan-Pavlovic and Nadja, 1998).

Angiography

Despite a negative screening test, renovascular disease may still be present, particularly if the lesion is in the distal or intrarenal portion of the artery. Both conventional renal angiography and intra-arterial DSA remain the gold standard for diagnosing renovascular disease and are indicated if the clinical index of suspicion is high and intervention is contemplated, regardless of the outcome of the screening tests and in lieu of contrast CT angiography and MRA with gadolinium in the high-risk patient (Mann and Pickering, 1992; Canzanella and Textor, 1994). Intra-arterial DSA allows less radiocontrast to be administered (25 to 50 mL vs. 100 mL) than with a conventional renal angiogram and is thus particularly advantageous in those with underlying renal insufficiency. Although intravenous DSA is less invasive than an arterial study and does not pose a risk for cholesterol embolization, it is

less desirable because the amount of required radiocontrast is higher (150 to 200 mL) and the visualization of the renal vasculature is poorer, thus resulting in both a lower sensitivity and a lower specificity (<90%) (Working Group on Renovascular Hypertension, 1987; Dunnick et al, 1989). Digital angiography using carbon dioxide in place of radiocontrast material may provide imaging similar to that with radiocontrast studies (although the distal vasculature may not always be adequately visualized) and also might avoid the potential for radiocontrast-induced nephrotoxicity; however, this procedure is not universally available (Hawkins et al, 1994).

KEY POINTS: ANGIOGRAPHY

- MRA with gadolinium may be used as a noninvasive test to assess the functional significance of a renal vascular lesion.
- It is highly sensitive and specific.
- Its usefulness in a patient with unstable renal function or a creatinine clearance of less than 30 mL/min is limited because of concerns regarding nephrogenic systemic fibrosis.
- Spiral CT angiography is considered to be a sensitive and specific test, but it is limited in its usefulness as a screening technique in patients with renal insufficiency.
- Duplex Doppler ultrasonography, although it provides many advantages, is time-consuming, highly operator dependent, and a technically difficult test to perform, which limits its use.
- Conventional renal angiography and intra-arterial DSA remain the gold standard for diagnosing renal vascular disease.

PATHOLOGY OF RENOVASCULAR HYPERTENSION

The two main causes of renovascular hypertension are atherosclerosis and fibrous dysplasia. Atherosclerosis accounts for 70% of all renal arterial lesions (Novick et al, 1996). The remaining lesions are caused by fibromuscular dysplasia, with women being most commonly affected (Table 45-1) (Pohl, 1999; Olin et al, 2012).

Atherosclerotic renal artery disease predominantly affects men and women aged 40 to 70 years. The proximal third of the renal artery is usually involved, and in 70% to 80% of the patients there is an aortic plaque that is impinging on the renal ostium, whereas the remaining 30% exhibit nonostial narrowing usually 1 to 3 cm distal to the renal artery ostium (Pohl, 1999). It has been observed that renal arteries with greater degrees of stenosis will more likely and more quickly progress to complete occlusion. Schreiber and colleagues (1984) noted that of 18 patients presenting with RAS, of 75% to 99% on an initial angiogram, 39% progressed to complete occlusion in 13 months. This contrasts with patients who had less than 50% stenosis and 50% to 75% stenosis that progressed to complete occlusion in 59 and 23 months, respectively (Table 45-2) (Schreiber et al, 1984).

Olin and associates (2012) enrolled 447 patients from 9 different sites in the United States Registry for Fibromuscular Dysplasia and reported their results. Ninety-one percent of their patients were female with a mean age at diagnosis of 51.9 years (range 5 to 83 years). Various arteries were involved, with the renal artery being the most common in 294 (66%) of the patients; next was the extracranial carotids in 251 (56%) of the patients; and least common was the vertebral arteries in 82 (18%) of the patients. The most common presenting symptoms were hypertension, headache, and pulsatile tinnitus. There was often a past or present history of vascular events: 19.2% with a transient ischemic attack or stroke, 19.7% with arterial dissections, and 17% with aneurysms.

Hypertension, aneurysm, and arterial dissection were the most common indications for intervention in these patients (Olin et al, 2012).

There are four types of fibrous dysplasia: medial fibroplasia, perimedial fibroplasia, intimal fibroplasia, and medial hyperplasia. Medial, perimedial, and intimal fibroplastic lesions may affect the renal artery with an incidence of 30%, 5%, and 5%, respectively, and they represent 70% to 85%, 10% to 25%, and 10%, respectively, of all fibrous renal artery diseases (Table 45-3) (Pohl, 1999). Medial hyperplasia, the fourth type of fibrous dysplasia, constitutes only 2% to 3% of all fibrous dysplastic lesions.

Medial fibroplasia occurs almost exclusively in women between 25 and 50 years of age. This lesion has the characteristic “string of beads” appearance on angiography and usually will involve both renal arteries. The lesions involve the distal half of the main renal artery and may extend into the branches. Histologically, the lesions are characterized by the growth of fibroblasts in the media covered by fibrous connective tissue in the stenotic areas and thinned-out medial tissue in the aneurysmal areas, thus creating the string-of-beads appearance on angiography (Fig. 45-5) (Pohl, 1999). These patients are not likely to progress to complete occlusion, nor are they likely to experience a decrease in their overall renal function (Novick and Fergany, 2002).

TABLE 45-1 Classification of Renal Artery Disease

Perimedial fibroplasia also occurs almost exclusively in women, but they are younger (between 5 and 15 years of age) (Olin, 2007). The stenosis occurs classically in the midrenal artery, although it may extend into the distal renal artery and its branches. Similar to medial fibroplasia, angiography may demonstrate a string of beads. However, unlike medial fibroplasia, the aneurysmal “beads” in perimedial fibroplasia never exceed the diameter of the main renal artery. Histologically, there is widespread collagen deposition in the outer half of the media. If left untreated, perimedial fibroplasia often progresses to renal occlusion and loss of renal function (Fig. 45-6) (Pohl, 1999; Olin 2007).

Intimal fibroplasia accounts for 10% of the cases of fibromuscular dysplasia and occurs predominantly in children and younger adults (Pohl, 1999; Novick and Fergany, 2002). Histologically, there is collagen deposition within the intimal arterial layer (Olin and Sealove, 2011). This form of fibroplasia may be complicated by disruptions of the internal elastic lamina and hence may result in dissection, arterial wall hematoma, and renal infarction (Olin, 2007). The lesions are usually in the proximal renal artery; however, they may also occur in the mid- or distal renal artery and without intervention are likely to progress and result in loss of renal function (Fig. 45-7) (Pohl, 1999).

Medial hyperplasia is a rare disease, often angiographically indistinguishable from intimal fibroplasia. Histologically, there is smooth muscle cell hyperplasia with no associated fibrosis (Olin, 2007).

PHYSIOLOGIC SIGNIFICANCE

Because not all renal artery lesions will result in hypertension, the physiologic significance of a lesion should be made before undertaking any therapeutic intervention to eliminate or control hypertension (Ploth, 1995). Renovascular hypertension is more likely to be observed when the lesion is greater than or equal to 70% in one or both renal arteries or when a 50% stenosis with poststenotic dilatation is demonstrated. The clinical significance of a lesion may be determined by ACE-inhibitor scans (see previous description), the pressure gradient across the renal

KEY POINTS: PATHOLOGY OF RENOVASCULAR HYPERTENSION

- There are four types of fibrous dysplasia: medial fibroplasia, perimedial fibroplasia, intimal fibroplasia, and medial hyperplasia.
- Medial fibroplasia is the most common lesion and typically presents with a characteristic “string-of-beads” appearance.
- These patients are not likely to show progression of the occlusion or to experience a decrease in overall renal function.
- Perimedial fibroplasia and intimal fibroplasia, however, are likely to progress if left untreated, resulting in loss of renal function.

artery, and by renal vein renin (RVR) measurements (Working Group on Renovascular Hypertension, 1987; Setaro et al, 1991; Mann and Pickering, 1992; Canzanello and Textor, 1994; Derkx and Schalekamp, 1994).

A significant pressure gradient (>10 to 15 mm Hg) across a renal artery lesion, which can be ascertained during intra-arterial renal angiography, may predict a reduction in BP with revascularization, whereas those without a significant gradient do not.

An RVR ratio of greater than or equal to 1.5 (affected/nonaffected side) may be observed when the lesion is the cause of “renin-dependent” hypertension. Unfortunately, the clinical utility of the RVR ratio is limited because in as many as 60% of patients, an improvement in BP may be seen following revascularization even in the absence of RVR lateralization; the RVR ratio is of poor predictive value in those with bilateral disease, it requires renal vein

catheterization with the administration of radiocontrast, and it necessitates the discontinuation of antihypertensives that may alter renin secretion.

Therefore, because the physiologic significance of a renal artery lesion may not always be reliably assessed, the clinician may often need to assume a causal relationship between the lesion and hypertension when one or more of the clinical features are present, as previously outlined.

KEY POINTS: PHYSIOLOGIC SIGNIFICANCE

- One may not always be able to assess reliably the significance of a renal arterial lesion before intervention.
- The clinician therefore may need to assume a causal relationship between the lesion and the presence of hypertension.

MANAGEMENT OF RENOVASCULAR HYPERTENSION

When a diagnosis of renovascular hypertension is made, BP control may be attempted with medical therapy alone, and/or with percutaneous transluminal renal angioplasty (PTRA) (with or without stenting), or with surgery. The type of lesion (atherosclerotic or fibromuscular), its site and the extent of the renal artery involvement, the overall medical status of the patient, and the inherent risks, as well as the skill of those performing the interventional procedures, determine the best therapeutic approach.

Medical Therapy

Control of BP in those with renovascular hypertension may be achieved in more than 90% of patients with medical therapy alone. Because of the severity of the hypertension, however, therapy generally requires multiple antihypertensive medications. Although all classes of antihypertensives may be used, drugs that inhibit AII production (ACE inhibitors) or block its receptor site (ARBs) have been shown to be particularly efficacious because the hypertension is often the result of activation of the renin-angiotensin system (Franklin and Smith, 1985; Hollenberg, 1987; Imamura et al, 1995; Tullis et al, 1999; Dworkin and Cooper, 2009). When used as monotherapy, ACE inhibitors may control BP in 80% of patients, and when combined with a diuretic, control may be increased to almost 90% (Franklin and Smith, 1985; Hollenberg, 1987).

Despite BP control with medical therapy, several studies have shown that atherosclerotic renal artery lesions may progress with time. It has been noted in studies that 40% to 60% of patients have progression of their atherosclerotic renal artery lesions throughout 7 years, with half of these progressing within 2 years (Schreiber et al, 1984; Pohl and Novick, 1985; Rimmer and Gennari, 1993). Those patients with an initial stenosis greater than or equal to 75% had the fastest rate of progression, with total occlusion occurring in 40% of the lesions (Pohl and Novick, 1985). In a prospective study using serial duplex ultrasonography, 295 arteries in 170 patients were examined throughout a mean of 33 months follow-up (Caps et al, 1998a). In 91 (31%) of the 295 renal arteries, the atherosclerotic lesions progressed with time at a rate directly proportional to the severity of the lesion at baseline. Twenty-eight percent of those with less than or equal to 60% stenosis and 49% of those with greater than or equal to 60% stenosis at baseline progressed, and total occlusion was observed in 9 with "severe" stenosis ($\geq 60\%$) at baseline.

Medical therapy may reduce BP below a critical level and induce ongoing renal ischemia distal to the arterial lesion, resulting in tubular atrophy, interstitial fibrosis, glomerulosclerosis, and progressive loss of function in the affected kidney(s) (see *Angioplasty and Stenting for Preservation of Renal Function*) (Michel et al, 1986; Hricik and Dunn, 1990). These changes are more likely to be observed with antihypertensives that inhibit angiotensin or block its receptors than with others; however, this has not been uniformly seen in clinical practice (Michel et al, 1986; Hricik and Dunn, 1990; Strandness, 1994; Caps et al, 1998b; van de Ven et al, 1998). Nevertheless, renal function should be closely monitored whenever such antihypertensive agents are used in patients with renovascular hypertension, particularly when they are combined with a diuretic. In addition to monitoring the serum creatinine concentration and estimated GFR or creatinine clearance, renal sizes and cortical blood flow velocity by duplex scanning should be assessed, because they may more quickly provide evidence of irreversible nephron loss (Caps et al, 1998b). Both ACE inhibitors and ARBs, particularly in the setting of volume contraction, may also result in acute (usually reversible) renal failure in 10% to 20% of those with either bilateral RAS or RAS affecting a solitary kidney (van de Ven et al, 1998).

The lesions of medial fibroplasia, the most common form of fibromuscular dysplasia, unlike atherosclerotic disease, rarely progress. However, the less common forms of fibromuscular dysplasia

(perimedial fibroplasia, medial hyperplasia, and intimal fibroplasia) may progress and result in loss of renal function (Schreiber et al, 1984; Pohl and Novick, 1985). Thus patients with these lesions must also be monitored closely (Pohl and Novick, 1985).

KEY POINTS: MEDICAL THERAPY

- Control of BP in those with renal vascular hypertension may be achieved in the vast majority of patients with medical therapy alone.
- Despite BP control with medical therapy, studies have shown that atherosclerotic renal artery lesions may progress with time.
- Careful monitoring of renal function, particularly when using ACE inhibitors and ARBs, must be maintained.

Angioplasty and Stenting for Hypertension

Percutaneous transluminal renal artery angioplasty (PTRA) is an angiographic technique by which stenotic renal arteries are dilated with a balloon-tipped catheter. Lesions that are most amenable to PTRA include those that are less than 10 mm in length, are partially occluded, and do not involve the ostium (Geyskes, 1988; Marshall et al, 1990). Following successful PTRA, an improvement in BP may be seen as quickly as 4 to 6 hours after the procedure but is more commonly seen after 48 hours, although the maximal antihypertensive effect may not be observed for several weeks (Bonelli et al, 1995; Ram et al, 1995). In general, the absence of an early antihypertensive response suggests that a long-term improvement of hypertension is unlikely (Bonelli et al, 1995).

PTRA without stenting has proved successful for patients with underlying fibromuscular dysplasia. Previously, surgical revascularization was the only option. It has primarily been used in those with recent onset of hypertension, those with poorly controlled hypertension despite medical therapy or who are unable to tolerate medical therapy, and in those with evidence of ischemic nephropathy (Slovut and Olin, 2004). Compared with surgery, it is less costly, less invasive, may be performed in the outpatient setting, has a lower morbidity rate, and does not preclude surgical revascularization if unsuccessful. The technical success rate of PTRA in experienced hands ranges from 87% to 100%, and improvement or cure of the hypertension has been reported to occur in close to 90% in many of the larger studies (Geyskes, 1988; Canzanella et al, 1989; Ramsay and Waller, 1990; Libertino and Beckmann, 1994; Aurell and Jensen, 1997; Slovut and Olin, 2004; Mousa et al, 2012). Although successful, a restenosis rate of up to 27% may be seen and periodic surveillance with duplex Doppler sonography should be performed to monitor for disease progression, restenosis, or loss of renal mass (Slovut and Olin, 2004).

Successful PTRA in patients with unilateral atherosclerotic RAS is technically more difficult to achieve (technical success rates may be as low as 70%), and rates of cure or long-term improvement of hypertension have not been consistent (Geyskes, 1988; Canzanella et al, 1989; Ramsay and Waller, 1990; Libertino and Beckmann, 1994; Aurell and Jensen, 1997; Nordmann et al, 2003). Although cure or long-term improvement of hypertension has been reported to be as high as 60% to 70% by some, these were observed in uncontrolled trials and the site of the renal artery lesion, which is of critical importance in determining the clinical outcome, varied. This was demonstrated by Canzanella and colleagues, in which an improvement of hypertension was seen in 86% of patients with unilateral nonostial lesions as compared with 46% with unilateral ostial lesions (Canzanella et al, 1989). Further, three prospective studies comparing PTRA with medical therapy for unilateral RAS demonstrated limited benefit regarding BP control and rates of renal or cardiovascular morbidity and mortality (Plouin et al, 1998; Webster et al, 1998; van Jaarsveld et al, 2000). The

potential benefit of PTRA is further diminished by the development of reversible acute renal failure in approximately 20% of patients and with thrombosis, perforation, or dissection of the renal arteries and/or diffuse atheroembolism occurring in 15% undergoing the procedure.

The effects on BP following PTRA in patients with bilateral RAS have been disappointing as well, in part, because of the frequent presence of ostial or completely occluded lesions (Canzanella et al, 1989; Marshall et al, 1990; Ramsay and Waller, 1990). These lesions are difficult to dilate, and attempts are associated frequently with high complication rates. In general, the selection criteria for patients and the type of lesions in which PTRA has been performed are poorly delineated in most studies. When performed for bilateral RAS, PTRA may be technically unsuccessful in as many as 60%, and, when successful, cure rates of hypertension may be as low as 8% and improvement in BP seen in only 43% (Ramsay and Waller, 1990). Further, because total occlusion of the renal artery in an atrophic kidney may be seen 50% of the time, few are cured of their hypertension, and only 14% experience long-term improvement of their BP when PTRA is attempted in patients with bilateral RAS associated with an atrophic kidney (Geyskes, 1988).

Even when technically successful, the restenosis rate following PTRA is significant (30% for nonostial and 50% for ostial lesions) and may occur shortly after the procedure (15% to 30% within 2 years) with recurrence of uncontrolled or accelerated hypertension.

Intravascular stenting of atheromatous RAS has been performed at the time of angioplasty in an effort to reduce the incidence of restenosis and to improve BP control. With increasing experience throughout the years, successful stent placement can be achieved in close to 100% of patients (Rees et al, 1991; van de Ven et al, 1995; Iannone et al, 1996; Tuttle et al, 1998). Despite this high rate of technical success, the restenosis rate remains at about 15% to 25%, and this condition might occur as early as 5 months after placement of the stent (Kidney and Deutsch, 1996; Rocha-Singh et al, 2005). When comparing PTRA with stenting and PTRA alone, van de Ven and coworkers demonstrated an 88% success rate in achieving renal artery patency (defined as a residual stenosis <50%) with PTRA with stenting as compared with a 57% patency rate in those who underwent PTRA alone for their ostial RAS (defined as a stenosis >50% within the first 10 mm of the aortic lumen) (van de Ven et al, 1999). At 6 months, the primary patency rate, as determined by angiography, remained significantly greater (75% vs. 29%) and the observed rate of restenosis was also less (14% vs. 48%) in the group assigned to PTRA with stenting. Despite the fact that a better revascularization was achieved with PTRA with stenting, there was no statistically significant difference in the BP between the two groups. However, many of the patients (29%) assigned to PTRA without stenting subsequently underwent stenting for either primary or late failure of their initial procedure. These patients were included in the analysis of the PTRA group, and thus the actual BP may have been more favorable for the stented group.

Improvement of BP has also been observed by some in those who are stented after unsuccessful PTRA as well as in those in whom primary endovascular stenting (without concomitant PTRA) has been performed for atherosclerotic RAS (Dorros et al, 1995, 1998a, 1998b; Blum et al, 1997; Rocha-Singh et al, 2005). Blum and colleagues (1997) noted a cure or improvement of hypertension in 78% of 68 patients in whom stents were placed for ostial lesions after unsuccessful PTRA. However, only 64% were followed for 12 months and only 9% for 60 months in this study. In the nonrandomized study by Rocha-Singh and associates, 208 patients with de novo or restenotic aorto-ostial renal lesions that were greater than or equal to 70% underwent stenting after unsuccessful PTRA, and an improvement of hypertension was noted at both 9 and 24 months. In those who underwent primary stenting for either unilateral or bilateral disease, Dorros and colleagues (1998a, 1998b) observed a cure or improvement of hypertension in 60% of their patients at 6 months; however, the number of patients with nonostial lesions was not specified in their study, and by 1 and 4 years follow-up, overall improvement in BP control declined to 42% and

only 1% remained cured. A more recent retrospective review by Corriere and coworkers, however, demonstrated only 1.1% of their 99 patients to be cured of their hypertension, and only 20.5% to demonstrate an improvement in their BP following primary stenting of 110 atherosclerotic renal artery lesions with a mean stenosis of $79.2 \pm 12.9\%$ during their short-term follow-up (Corriere et al, 2008). Further, other studies have noted no significant improvement in BP control after either primary or secondary stenting (Harden et al, 1997; Tuttle et al, 1998).

Although the results of many earlier studies suggest that PTRa with stenting may cure or improve control of hypertension, three more recent randomized studies raise questions about the effectiveness of revascularization with stenting for BP control. The Stent Placement and Blood Pressure and Lipid-lowering for Prevention of Progression of Renal Dysfunction Caused by Atherosclerotic Ostial Stenosis of the Renal Artery (STAR) trial enrolled 140 patients with BP controlled to less than 140/90 mm Hg, and with a renal ostial lesion greater than 50%, and prospectively randomized the patients to either renal artery stenting and medical therapy or medical therapy alone. At the end of follow-up, **there was no difference in the degree of BP control** (Bax et al, 2009). It should be noted, however, that 12 of the 64 patients who were randomized to stenting were found to have an ostial lesion less than 50% and were not stented, but they were included in the analysis of the stented group and thus may have negatively impacted the findings of the study (Bax et al, 2009). In the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial, 806 patients with atherosclerotic RAS were randomized to undergo revascularization and medical therapy or to undergo medical therapy alone (ASTRAL Investigators et al, 2009). As in the STAR trial, this study has also been criticized for including patients who did not have clinically significant RAS and who did not have their findings confirmed by core laboratories. After a median follow-up of 34 months, **there was no difference in BP control between the two groups**, although the number of antihypertensive medications required was slightly higher in the medically managed group.

The Cardiovascular Outcomes and Renal Atherosclerotic Lesions (CORAL) study was designed to overcome, and for the most part did overcome, the shortcomings of previous studies (Cooper et al, 2014). In short, this was a multicentered, open-label, randomized controlled trial that compared medical therapy alone with medical therapy plus renal artery stenting in patients with atherosclerotic RAS and elevated BP, chronic kidney disease, or both. **Medical therapy consisted of an ARB, a calcium channel blocker, a statin, a diuretic, and other medications as necessary.** The study sponsors supplied drugs. (Other specific details regarding the protocol and its limitations are discussed under Angioplasty and Stenting for Preservation of Renal Function.) Severe RAS was defined angiographically as a stenosis of at least 80% but less than 100% of the diameter, or stenosis of at least 60% to less than 80% of the diameter, of an artery with a systolic pressure gradient of at least 20 mm Hg. Because of enrollment constraints, the actual average percent stenosis was 73%. The primary end points of the study were occurrences of major cardiovascular or renal events. The study was not specifically designed to determine whether or not stenting would confer an additional benefit on BP control. The average systolic BP was 150 mm Hg at enrollment, and participants, on average, were taking a mean of 2.1 antihypertensive medications. Overall, a reduction of systolic BP of a mean of 15 to 16 mm Hg was achieved in both groups with an average of 3.4 medications, **not different in either group.** However, a modest, but statistically significant, reduction of 2 mm Hg in systolic BP with stenting was noted. However, **this reduction did not translate into a significant decrement in clinical events.** Therefore the risk of stenting in the group of patients studied does not seem worth the potential benefit regarding BP control.

It is important to note, however, that **patients with accelerated hypertension, flash pulmonary edema, and malignant hypertension were not included in this trial.** Therefore conclusions regarding these groups of patients cannot be drawn from this study. The approach to these patients must be individualized, and

the clinician must decide which patients may benefit from intervention.

The American College of Cardiology/American Heart Association (ACC/AHA) guidelines were published before the publication of the results of the CORAL trial. They are as follows: PTRa is a reasonable option for (1) patients with a hemodynamically significant RAS and accelerated hypertension or malignant hypertension, (2) hypertension with an unexplained unilateral small kidney, (3) hypertension with intolerance to medication, and (4) renal stent placement that is indicated for ostial lesions that meet the clinical criteria for intervention (Hirsch et al, 2006).

Given the results of the CORAL trial, this panel may reconsider recommendation numbers 2 and 4 because these patients may have an “equivalent” response to medical therapy without the attendant risks that occur with stenting.

Previous unblinded studies have suggested that catheter-based renal artery denervation reduces BP in patients with resistant hypertension. This approach until recently would have been an alternative to medical therapy in patients with renal vascular hypertension who did not respond adequately to medical therapy and were facing transluminal angioplasty as an alternative. However, the results of the Simplicity trial have been published (Bhatt et al, 2014). A total of 535 patients underwent randomization. The patients were divided into two separate groups. They were randomly assigned in a 2 to 1 ratio to undergo renal denervation or a sham procedure. This prospective, blinded study did not show a significant reduction in systolic BP in patients with resistant hypertension who underwent the actual denervation procedure versus those who had a sham operation. Unfortunately, this option regarding the treatment of resistant hypertension is no longer tenable based on this well designed, randomized controlled trial (Bhatt et al, 2014).

KEY POINTS: ANGIOPLASTY AND STENTING FOR HYPERTENSION

- In general the effect on BP control following PTRa has been disappointing.
- Three recent trials have shown no significant difference between medically treated patients and those treated with transluminal angioplasty.
- The most recent and best-performed trial is the CORAL study that showed only a 2 mm Hg difference in BP between groups. This, however, did not translate into a significant decrement in clinical events, and it exposed the patients to the potential risks of angiography.
- Patients with accelerated hypertension flash pulmonary edema and malignant hypertension were not included in this trial. Therefore conclusions regarding these patients cannot be drawn from this or other studies.
- Renal denervation for resistant hypertension has been recently shown to be unsuccessful (SIMPLICITY trial).

Although generally safe, a 5% to 15% complication rate may be seen with PTRa or stenting. The majority of these are of minor significance and are the results of hematoma formation at the puncture site or renal spasm. However, when severe, renal artery spasm may result in local thrombosis and renal infarction, but this can usually be reversed or prevented by intra-arterial infusion of nitroglycerin. Major complications, such as reversible acute renal failure associated with radiocontrast, have been observed in approximately 20% of cases; renal artery perforation, occlusion, dissection, and irreversible acute renal failure resulting from atheroembolization are less frequent (<5%). The deployment of endovascular stents may also be complicated by malpositioning or dislocation.

Angioplasty and Stenting for Preservation of Renal Function

The lesions of atherosclerotic RAS progress with time, but it is unclear how many patients ultimately develop ischemic nephropathy or ESRD as a consequence of their vascular lesions. The rate at which these renal complications occur is also unknown.

In a retrospective study by Baboolal and colleagues (1998), the clinical course of 51 patients with significant bilateral RAS (defined as total occlusion or $\geq 90\%$ stenosis in one renal artery and $\geq 50\%$ stenosis in the contralateral artery) who were receiving medical therapy alone was examined. These patients were treated medically because of physician or patient preferences, because the lesions were thought not to be amenable to PTRAs, because the kidneys were thought to be too small and nonsalvageable, or because the operative risks were deemed too great. As a whole, the GFR fell 4 mL/min/yr (range 1 to 16 mL/min/yr), and at 5 years of follow-up ESRD developed in only 12%. ESRD occurred in those who had the most significant renal impairment (mean GFR 25 mL/min, range 15 to 56 mL/min) at the time of angiography and in whom the decline in GFR was most rapid (mean 8 mL/min/yr, range 3 to 13 mL/min/yr). Thus, despite the presence of significant RAS in all of the patients, a significant number showed either little or no change in their renal function throughout time, and 88% did not require renal replacement therapy. These findings suggest that even in the presence of significant renal artery disease, sufficient renal collateral circulation may develop to maintain adequate RBF and renal viability (Meyrier et al, 1998).

Progressive deterioration in renal function does occur, however, in a subset of patients with atherosclerotic RAS and is an increasing cause of potentially reversible renal insufficiency in the elderly as well as the primary cause of renal failure in 10% to 20% of the ESRD population (Jacobson, 1988; Rimmer and Gennari, 1993; Mailloux et al, 1994; Greco and Breyer, 1997; Middleton, 1998; Textor, 1998; van Ampting et al, 2003).

Despite renal replacement therapy, mortality rates in these individuals are greater than 50% throughout 3 years, and the 5- and 10-year survival rates are only 18% and 5%, respectively. Given the increasing number of these patients and their poor prognosis with renal replacement therapy, it is imperative that revascularization and restoration of renal function be pursued whenever there is clinically significant worsening of renal function. However, avoiding renal replacement therapy per se does not guarantee a longer survival in these patients who usually present with diffuse vascular disease.

PTRA without stenting has been shown to improve renal function in 40% and to stabilize renal function in another 30% to 40% of those with ischemic nephropathy (Canzanella et al, 1989; Sos, 1991; O'Donovan et al, 1992; Rimmer and Gennari, 1993; Greco and Breyer, 1997). These results were primarily obtained in those with nonostial lesions, and although the restenosis rate may be as high as 10% to 30%, many are amenable to repeat PTRAs (Greco and Breyer, 1997). PTRA in patients with nonostial lesions shows a success rate similar to that of surgical revascularization and poses a lower risk of morbidity and mortality. In the presence of ostial lesions, which comprise the vast majority (80% to 85%) of atherosclerotic RAS, PTRA without stenting is far less successful and effective; thus most PTRAs for atherosclerotic RAS are performed with endovascular stent placement. Endovascular stents have been placed at the time of PTRA or "primarily" (without previous PTRA) (Dorros et al, 1995, 1998a, 1998b; Boisclair et al, 1997; Harden et al, 1997; Rundback et al, 1998; Isles et al, 1999; Rees, 1999; Ives et al, 2003; Korsakas et al, 2004; Corriere et al, 2008). In these earlier studies, stenting resulted in improved renal function in 30% to 40% and stabilization of renal function in another 30% to 50%. Long-term outcomes of stenting in those with ischemic nephropathy suggested that the clinical benefit was inversely related to the level of renal function at the time of the procedure, with the greatest overall benefit observed in those with a baseline serum creatinine concentration of 1.5 to 2.0 mg/dL. Most of these studies, however,

included patients with both ostial and nonostial atherosclerotic lesions, and, in some, the stenoses were greater than or equal to 50% and may not have necessarily been of hemodynamic significance.

Several investigators have studied the effect of stenting on renal function in patients with only ostial lesions (Rees et al, 1991; van de Ven et al, 1995; Blum et al, 1997; Tuttle et al, 1998; Rocha-Singh et al, 2005). In the earlier studies by Rees and van de Ven, approximately one third of patients demonstrated improved renal function following stenting, whereas stabilization of renal function was noted in 36% in the former study and 58% in the latter (Rees et al, 1991; van de Ven et al, 1995). Both studies, however, had only short-term follow-up (mean follow-up 6.5 and 9 months, respectively) (Rees et al, 1991; van de Ven et al, 1995). Researchers of three studies have examined the long-term effects of stenting on preservation of renal function in patients with ostial lesions (Blum et al, 1997; Tuttle et al, 1998; Rocha-Singh et al, 2005). In their study, Blum and coworkers (1997) found no deterioration in renal function in their 68 patients with ostial lesions with a mean serum creatinine concentration of 1.23 ± 0.6 mg/dL (range 0.5 to 3.9 mg/dL) during a mean follow-up of 27 months after stenting following unsuccessful angioplasty. Further, 30% of patients who exhibited significant renal insufficiency at baseline remained stable. Tuttle and colleagues (1998) followed 129 patients for a mean of 24 months after undergoing either primary or secondary stenting. No significant change was observed in the patients' creatinine clearances (as determined by the Cockcroft-Gault formula) despite the low level of renal function at baseline (range 23 ± 3 to 53 ± 3 mL/min); an improvement was noted in 15%, another 81% showed stabilization of their renal function, and, of the 8 patients initially dialysis dependent, 4 recovered significant renal function and had a serum creatinine of 2.3 ± 0.5 mg/dL at 15 ± 6 months (range 9 to 24 months) (Tuttle et al, 1998). In the nonrandomized study by Rocha-Singh and coworkers (2005), 208 patients with de novo or restenotic aorto-ostial RAS greater than or equal to 70% underwent stenting after unsuccessful PTRA. At 9 and 24 months follow-up, the serum creatinine concentration remained unchanged from baseline values.

Although suggestive of benefit, all of the aforementioned studies were limited by the absence of a control group that was treated with medical therapy alone and by the fact that it was not clear if endovascular stenting was performed for the worsening of renal function. To date, three randomized studies have been performed to help clarify this issue. In the STAR trial, 140 patients with BP controlled to less than 140/90 mm Hg and with a renal ostial lesion greater than 50% were assigned to either renal artery stenting and medical therapy or to medical therapy alone. At 2 years, there was no statistical difference in the primary end point defined as a decline in creatinine clearance of greater than or equal to 20% between the two groups (Bax et al, 2009). One of the limitations of this study, however, was that 12 of the 64 patients who were randomized to stenting were found to have an ostial lesion less than 50% and were not stented, but they were included in the analysis of the stented group and thus they may have negatively impacted the findings of the study (Bax et al, 2009). Of the 806 patients with atherosclerotic RAS randomized to undergo revascularization and medical therapy or to medical therapy alone in the ASTRAL trial, no difference between the two groups was noted in the decline of renal function at 1 year (median follow-up of 34 months) (ASTRAL Investigators et al, 2009). Further, there were no differences in the outcomes based on the severity of stenosis at baseline, renal sizes, baseline-estimated GFR, the baseline serum creatinine concentration, or the rate of renal deterioration before randomization (ASTRAL Investigators et al, 2009). Similar to the findings of the STAR trial, the findings of the ASTRAL trial may have been unlikely to show a benefit from endovascular revascularization because 25% of those enrolled in the study experienced normal renal function, a significant number of patients exhibited only unilateral disease, and a significant percentage of the stenotic lesions were less than 70% and possibly of little hemodynamic significance.

As mentioned earlier, in the text regarding BP control, the findings of the CORAL trial have been published (Cooper et al, 2014). This was a multicenter, prospective, randomized, controlled study in which patients with difficult-to-control hypertension (defined as systolic BP greater than or equal to 155 mm Hg on two or more antihypertensives) or renal impairment less than 60 mL/min/1.73 m² by the Modification of Diet in Renal Disease (MDRD) formula, and RAS greater than 60% but less than 100%, were randomized to either optimal medical therapy alone or to optimal medical therapy and renal artery stenting. The participants in the CORAL trial were followed for the occurrence of adverse cardiovascular and renal events (a composite end point of death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive heart failure, progressive renal insufficiency, or the need for renal replacement therapy). Throughout a median follow-up of 43 months, no significant difference between the treatment groups in the rate of the individual components of the primary end point or in all-cause mortality was noted. Therefore renal artery stenting did not confer a clinically significant benefit with respect to the prevention of clinical events when added to comprehensive, multifactorial medical therapy in people with atherosclerotic RAS and hypertension or chronic kidney disease. Although the average percent stenosis was 73% overall, the investigators were unable to demonstrate a benefit among participants with RAS of more than 80% (Cooper et al, 2014).

The CORAL trial includes several strengths. Among these is the fact that the investigators created a protocol that maximized adherence to medical therapy by supplying medication and minimizing crossovers, and the fact that investigators demonstrated a 20% reduction of the primary end point at 2 years, which was half of the expected rate of 40%. They clearly demonstrated that high-quality medical therapy is of paramount importance in managing this disease. However, limitations of the study must be noted:

1. Patients with a serum creatinine of greater than 4 mg/dL were excluded.
2. Patients with a renal artery lesion that could not be treated with the use of a single stent were excluded.
3. The median percent stenosis was 73%. All patients with RAS of greater than 60% were treated, although some of these may not have been hemodynamically significant.
4. No data are provided regarding the rate of decline of renal function before enrollment into the trial.
5. The population may represent a group of patients in whom medical therapy was superior to that seen in general practice because medications were supplied to the patients.
6. A subgroup of patients may well have been excluded from the study by their physicians and sent for stenting based on their own individual practice guidelines. These patients may have had “uncontrollable” or malignant hypertension in spite of medications, or intolerance to medications, or rapidly deteriorating renal function.

As stated in an accompanying editorial, the CORAL trial struck a balance between the practical constraints of patient recruitment and the most appropriate target population for renal artery stenting. To succeed in recruiting a sufficient number of patients to achieve statistical power, patients with stenoses of at least 60% were allowed into the trial. Again, it is important to note that when patients with greater than 80% stenosis were analyzed as a subgroup, there was no difference when compared to those patients in whom less severe stenosis was observed. A more restrictive trial in patients with critical bilateral disease or a severe stenosis involving a single functioning kidney will likely never be completed. **Therefore it remains important to identify a target population with severe renal insufficiency that may benefit from intervention.** Patients who in fact have a serum creatinine of greater than 4 mg/dL, but had rapid deterioration of renal function before the time of presentation, may respond to intervention with stenting to preserve renal function. There are reports of patients who have been able to discontinue hemodialysis after renal artery stenting is performed for ischemic nephropathy. Thus salvaging renal function and control of BP

remains an issue in a proportion of patients with renal artery occlusive disease. In the majority of these patients, in general, stenting is the least invasive and most appropriate therapy. However, depending on the location of the lesion and/or its size and whether or not it is associated with lesions in the abdominal aorta or is a subtype of fibromuscular dysplasia, surgery may be the more appropriate treatment choice. (See Surgical Treatment of Renal Artery Stenosis).

Given the results of the CORAL trial, in which patients may or may not have had stable renal function, the indications for PTR for preservation of renal function outlined by the ACC/AHA remain reasonable. As per their guidelines, PTR is to be considered in patients with RAS and progressive chronic kidney disease with bilateral RAS or RAS to a solitary functioning kidney, particularly in those in whom there has been a rapid decline in renal function, without another clear cause, for the preceding 3 to 6 months (Hirsch et al, 2006).

There appears to be a “window of opportunity” defined by a serum creatinine level between 1.5 mg/dL and 3 mg/dL for most interventions to be successful. Waiting for advanced renal failure to develop diminishes the likelihood that renal function will improve after revascularization. Conversely, patients with near-normal renal function and well-controlled hypertension gain relatively little from intervention. As summarized by the authors of the CORAL trial, renal artery stenting appears not to confer a significant benefit with respect to the prevention of clinical events when added to comprehensive, multifactorial medical therapy in individuals with atherosclerotic RAS and hypertension or chronic kidney disease (Cooper et al, 2014).

Before undertaking revascularization for the preservation of renal function, an assessment of the likelihood of significant functional renal recovery should be assessed. In general, **improvement or stabilization of renal function is more likely to occur when the following guidelines are present (Novick et al, 1987):**

1. Visualization of the collecting system on an IVP or during the pyelogram phase of the angiogram
2. Kidney length greater than 9 cm
3. Evidence of collateral circulation filling the distal vasculature on the side of total renal artery occlusion during angiography
4. Demonstration of viable glomeruli on renal biopsy with minimal arteriolar glomerulosclerosis

Our approach to the treatment of hypertension and/or ischemic nephropathy is outlined in Figures 45-8 and 45-9.

KEY POINTS: ANGIOPLASTY AND STENTING FOR PRESERVATION OF RENAL FUNCTION

- Before the CORAL trial, most data in patients with ischemic nephropathy regarding improvement of renal function after angioplasty were limited by the absence of control groups and prospective randomization.
- The CORAL trial was a definitive, prospective, randomized control trial comparing medical therapy alone versus medical therapy with transluminal angioplasty with stenting, and it did not show any significant difference between the treatment groups in the rate of deterioration of renal function.
- There remains a subgroup of patients that may benefit from percutaneous transluminal angioplasty in addition to medical therapy (rather than medical therapy alone), because the CORAL trial did include some limitations.

Surgical Treatment of Renal Artery Stenosis

With the advent of ACE inhibitors, angiotensin receptor blockade, statins, and PTR, the need for surgical revascularization and reconstruction of the renal artery has diminished. As discussed previously in this chapter, the CORAL trial is likely to alter the need

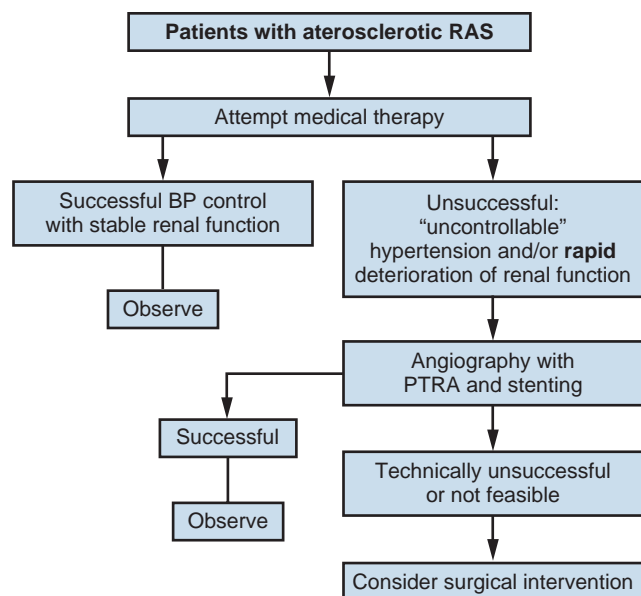

Figure 45-8. Algorithm for the management of patients with arteriosclerotic renal artery stenosis (RAS). BP, blood pressure; PTRA, percutaneous transluminal renal angioplasty.

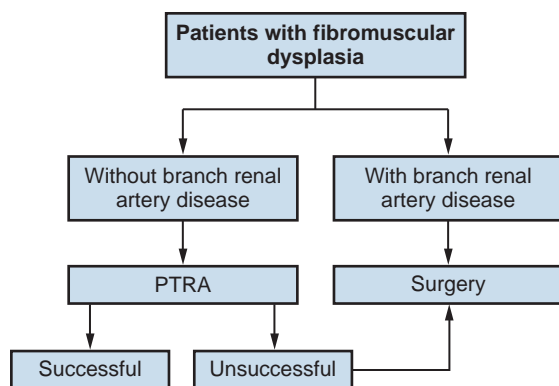

Figure 45-9. Algorithm for the management of patients with fibromuscular dysplasia. PTRA, percutaneous transluminal renal angioplasty.

for interventional treatment even further. However, an indication for surgical intervention in a select group of patients remains. Patients with RAS with concomitant aneurysmal or occlusive aortic disease, where surgery is indicated, would benefit from surgical intervention to correct both lesions if the aortic disease cannot be repaired without correcting the renal occlusive disease as well. Some surgeons may approach this by repairing the aortic disease with surgery and subsequently correct the renal artery lesion by PTRA when an indication for this intervention presents itself (Safian and Textor, 2001). Surgery is also indicated in patients who present with macroaneurysms of the renal artery associated with the stenosis because rupture of these lesions might occur if they are larger than 4 cm (Olin, 2007).

Because the CORAL trial recruited patients from primary physicians, it likely did not include patients who exhibited malignant/accelerated or uncontrollable hypertension, patients who did not tolerate medical therapy, or patients who showed rapid deterioration of renal function (1 to 6 months before presentation) with serum creatinines remaining between 1.5 and 3.0 mg/dL. These patients may well have been referred directly for an intervention. The intervention would have varied depending on the location of the lesion. PTRA would have been performed under most circumstances. However, if there was an ostial lesion greater than 10 mm,

the patient would likely have been referred for surgical revascularization. Therefore there remains a group of patients that will require surgical intervention.

KEY POINTS: SURGICAL TREATMENT OF RENAL ARTERY STENOSIS

- Although diminished, for specific patients the need for surgical revascularization of the renal artery remains.
- These patients include those with concomitant aneurysmal or occlusive aortic disease, those with macroaneurysms of the renal artery associated with stenosis, those with malignant or accelerated hypertension (with or without acute renal failure) who did not respond or cannot tolerate medical therapy, and those in whom transluminal angioplasty is technically impossible to accomplish.

The traditional criteria that will ensure the best outcome of surgical revascularization of a renal artery are (1) a kidney greater than 8 cm in length; (2) retrograde filling of the distal renal artery by collateral vessels on radiographic or scintigraphic imaging studies; (3) patency of the distal renal artery; (4) viability of the involved kidney on isotopic renography; and (5) minimal glomerular sclerosis and well-preserved tubules on renal biopsy (Garcia-Donaire and Alcazar, 2005).

Patients who require renovascular surgery often have comorbidities that make them a higher surgical risk. These comorbidities include angina (29.9%), previous myocardial infarction (27%), congestive heart failure (23.7%), cerebrovascular disease (24.8%), diabetes mellitus (18.1%), and claudication (56.4%) (Pohl, 1999). The morbidity of surgery can be diminished by the preoperative screening and correction of coronary and carotid arterial disease, excluding patients with severely diseased aortas. Aortorenal bypass is the preferred surgical technique in patients with atherosclerotic RVH when the abdominal aorta is not diseased. However, when the abdominal aorta has atherosclerotic plaques, alternative techniques for renal arterial bypass include splenorenal bypass for left renal arterial lesions, hepatorenal bypass for right arterial lesions, ileorenal bypass, bench surgery with autotransplantation of the involved renal unit, and the use of the supraceliac or lower thoracic aorta for the bypass as these are usually less involved by atherosclerotic disease. Some surgeons advocate performing unilateral revascularization in patients with bilateral disease to minimize patient operative morbidity (Pohl, 1999).

Acute Kidney Injury

Acute Tubular Necrosis

Clinical Approach to the Differential Diagnosis of Acute Kidney Injury

Management of Acute Kidney Injury

Chronic Kidney Disease

Disorders of renal function are ubiquitous in the contemporary practice of medicine. Current estimates suggest that kidney disease affects approximately 10% to 13% of the adult American population (Coresh et al, 2007), and thus awareness of the diagnosis and management of this disease has been the focus of the National Kidney Foundation (NKF) and other health care organizations (www.kidney.org). In 2002 the NKF published the Kidney Disease Outcomes Quality Initiatives (K/DOQI) Guidelines setting up the framework for the definition, diagnosis, classification, and management of kidney disease (National Kidney Foundation, 2002). Although these guidelines have been recently updated (Khwaja, 2012; KDIGO Committee, 2013; Levin and Stevens, 2014), the 2002 K/DOQI guidelines broadly grouped kidney disease into two major categories: acute kidney injury (AKI) and chronic kidney disease (CKD). These conditions are common in clinical practice, so urologists are likely to encounter issues related to renal function and its aberration on a daily basis. This chapter is designed to give a contemporary insight into the nature of kidney disease and its treatment.

ACUTE KIDNEY INJURY

Definition

AKI is defined as a rapid reduction in renal function characterized by progressive azotemia (best measured clinically by serum creatinine and blood urea nitrogen [BUN]), which may or may not be accompanied by oliguria. This abrupt decline in renal function occurs during the course of hours to days and results in the accumulation of byproducts of metabolism and the dysregulation of volume, acid/base, and electrolyte homeostasis. AKI can be diagnosed with certainty when the patient's previous renal function is known and the reduction in renal function is documented. Practice guidelines proposed by Kidney Disease: Improving Global Outcomes (KDIGO) (Khwaja, 2012) defined AKI when one of the following criteria was met:

1. An increase in serum creatinine greater than or equal to 0.3 mg/dL within 48 hours
2. An increase in serum creatinine greater than or equal to 1.5 times baseline within the previous 7 days
3. Urine volume less than or equal to 0.5 mL/kg/hr for 6 hours

A new system has been proposed for the staging of AKI according to severity (Table 46-1).

The cardinal feature of AKI is a decline in glomerular filtration rate (GFR). Although ideally determined by inulin or radioisotopic clearance techniques, it is usually identified in routine clinical practice by a rise in BUN or creatinine. **It is important to understand the limitations of these common clinical chemistries so that they can be properly interpreted. The correlation among BUN, creatinine, and GFR assumes they are delivered into the serum at a constant rate. Therefore conditions such as hypercatabolic state**

and massive trauma, which may be seen in surgical patients, can affect renal functional assessment. BUN may be disproportionately elevated in states of marked volume contraction, hypercatabolic states, and with marked increases in protein loads seen with gastrointestinal bleeding or total parenteral nutrition (TPN). Serum creatinine (SCr) is a normal metabolite of muscle that is produced at a constant rate and is an endogenous marker that is used as a surrogate of GFR. In certain situations, serum creatinine may overestimate kidney function. This is explained by the fact that serum creatinine is not only filtered by the glomeruli but also secreted by the renal tubule. Moreover, in nonsteady-state circumstances, such as in patients with AKI, increases in serum creatinine levels may lag behind the actual event of renal injury. A normal or slightly low serum creatinine level in a small or malnourished patient may result in an underestimation of the level of renal impairment. Because of this, creatinine-based estimation equations in the setting of AKI may not perform well. Methods based on timed urine collections such as urinary creatinine clearance (CrCl) or measured tracers (inulin, iothalamate, and so forth) are cumbersome to perform, and they result in average values that span the test duration (Hoste et al, 2005; Levey et al, 2007). Some have advocated the use of "real-time" estimates of GFR using infused radioisotopic plasma disappearance techniques for patients with AKI in the intensive care unit (ICU), but this use has not achieved wide clinical acceptance. In clinical practice the experienced clinician infers that the patient's true GFR is significantly impaired based on a rapidly rising SCr and the clinical picture.

AKI is a common problem in the contemporary practice of medicine and urology. Prospective studies have demonstrated that 2% to 5% of all patients admitted to a general medical/surgical hospital unit will develop AKI (Nolan and Anderson, 1998). In selected patients in the ICU following cardiovascular or abdominal vascular surgery, the incidence may exceed 20%. AKI is associated with significant morbidity (which prolongs hospitalization and increases costs) and mortality (Dimick et al, 2003). The high occurrence and substantial morbidity and mortality of AKI demand a logical approach to its early recognition and prevention, as well as prompt diagnosis and management of its complications.

Epidemiology and Classification of Acute Kidney Injury

It is clinically useful to separate the causes of AKI into three major categories: prerenal, intrarenal, and postrenal. Distinguishing among the three basic categories of AKI is a challenging clinical exercise. Assigning a patient to one of the three categories usually requires a combination of clinical and laboratory evaluations and may require invasive monitoring of central hemodynamics or imaging studies of the genitourinary tract. The importance of differentiating the major causes of AKI must be stressed because the initial evaluation and management are tailored to the particular cause. Because the greatest proportion of hospital-acquired AKI is

TABLE 46-1 Proposed KDIGO Staging of Acute Kidney Injury

STAGE	SERUM CREATININE	URINE OUTPUT
1	1.5–1.9 × baseline or ≥0.3 mg/dL (≥26.5 μmol/L) increase	<0.5 mL/kg/hr for 6–12 hr
2	2.0–2.9 × baseline	<0.5 mL/kg/hr for ≥12 hr
3	3 × baseline or ≥4.0 mg/dL (≥353.6 μmol/L) increase or initiation of RRT or in patients <18 yr a decrease in eGFR <35 mL/min/1.73 m ²	<0.3 mL/kg/hr for ≥24 hr or Anuria ≥12 hr

eGFR, estimated glomerular filtration rate; KDIGO, Kidney Disease: Improving Global Outcomes; RRT, renal replacement therapy.

From Khwaja A. KDIGO Clinical Practice Guidelines for Acute Kidney Injury. *Nephron Clin Pract* 2012;120(4):c179–84.

secondary to acute tubular necrosis (ATN), this chapter places special emphasis on the diagnosis, pathophysiology, and management of ATN. For example, an evaluation in Madrid reported 748 cases of AKI at 13 tertiary care hospital centers (Liano and Pascual, 1996). The causes of AKI were: 45% ATN, 21% prerenal, 13% acute or chronic kidney failure, 10% urinary tract obstruction, 4% glomerulonephritis/vasculitis, 2% acute interstitial nephritis (AIN), and 1% atheroembolic renal disease. AKI occurs more commonly in the surgical/trauma ICUs, medical ICUs, and postoperative units. A study by the American College of Surgeons National Surgical Quality Improvement Program has identified 11 independent preoperative predictors for the development of AKI including age 56 years or older, male gender, emergency surgery, intraperitoneal surgery, diabetes mellitus necessitating oral therapy, diabetes mellitus necessitating insulin therapy, active congestive heart failure, ascites, hypertension, mild preoperative renal insufficiency, and moderate preoperative renal insufficiency (Kheterpal et al, 2009).

Prerenal Azotemia

Prerenal azotemia is caused by transient renal hypoperfusion that may induce a fall in GFR and produce urinary sodium avidity. The hallmark of prerenal azotemia is its reversibility with treatment of the underlying cause and the lack of structural damage to the kidney. The “gold standard” is the response to appropriate fluid repletion or rapid reestablishment of normal renal hemodynamics, which will lead to the return of renal function to the previous baseline within 24 to 72 hours.

In normal circumstances, the kidney can maintain normal renal blood flow (RBF) and GFR down to systemic perfusion pressures of approximately 55 to 60 mm Hg (Walsh et al, 2013). The phenomenon of autoregulation consists of the intricate interplay of glomerulotubular feedback and myogenic response in afferent arterioles. In patients with CKD, hypertension, diabetes, and/or AKI, autoregulation is often compromised. In these circumstances, a reduction in GFR may occur with modest decrease in systemic pressure within what is otherwise considered normal range. In the setting of decreased renal perfusion, angiotensin II and vasodilatory prostaglandins play an important role in maintaining glomerular hydrostatic pressure and GFR. The three major determinants of GFR are renal plasma flow, glomerular hydrostatic pressure, and

BOX 46-1 Prerenal Causes of Acute Kidney Injury

VOLUME DEPLETION

Surgical: hemorrhage, shock
Gastrointestinal losses: vomiting, diarrhea, fistulae
Renal: overdiuresis, salt-wasting disorders

CARDIAC CAUSES: PRIMARY DECREASE IN CARDIAC OUTPUT

Acute disorders: myocardial infarction, arrhythmias, malignant hypertension, tamponade, endocarditis
Chronic disorders: valvular diseases, chronic cardiomyopathy (ischemic heart disease, hypertensive heart disease)

REDISTRIBUTION OF EXTRACELLULAR FLUID

Hypoalbuminemic states: nephrotic syndrome, advanced liver disease, malnutrition
Physical causes: peritonitis, burns, crush injury
Peripheral vasodilatation: sepsis, antihypertensive agents
Renal artery stenosis (bilateral)

glomerular permeability. Angiotensin II has selectively greater vasoconstrictor effects on the efferent than the afferent arteriole, whereas vasodilatory prostaglandins can cause afferent arteriolar vasodilation. **Drugs that selectively block angiotensin II synthesis, angiotensin-converting enzyme inhibitors (ACE inhibitors), and angiotensin receptor blockers (ARBs), or that inhibit vasodilatory prostaglandin synthesis such as nonsteroidal anti-inflammatory drugs (NSAIDs) (Whelton, 1999), may cause AKI.** This is prone to occur in clinical settings when GFR is already compromised (Toto et al, 1991; Whelton, 1999).

Prerenal azotemia may be encountered in both the volume-depleted and volume-overloaded patient (Box 46-1). True volume depletion may result from renal or extrarenal losses that result in systemic hypotension and renal hypoperfusion. In the volume-overloaded patient, with edematous states such as cirrhosis and congestive heart failure, prerenal azotemia may occur because the kidney perceives that the vascular system is underfilled (i.e., “ineffective arterial blood volume”). This results in renal hypoperfusion. Prerenal azotemia may also occur because of high-grade bilateral renal artery stenosis (RAS) or in states of renal hypoperfusion resulting from redistribution of extracellular fluid with peripheral vasodilation as seen with sepsis. As noted earlier, ACE inhibitors, ARBs, and NSAIDs may alter the vasoconstrictor effects of angiotensin II and the vasodilatory effects of prostaglandins to produce prerenal azotemia. This is especially the case in elderly patients with impaired GFR, subtle volume depletion, or occult RAS.

The pathophysiology of prerenal azotemia relates to the reduction in RBF. Renal hypoperfusion stimulates both the sympathetic nervous system (SNS) and renin-angiotensin system to cause renal vasoconstriction and sodium avidity. Furthermore, hypotension is a powerful stimulus to the release of an antidiuretic hormone, which mediates water reabsorption. Hence urine production is characterized by low volume, decreased concentration of urinary sodium, increased urinary excretion of creatinine, and a high urine osmolality. Microscopy of the urinary sediment is usually bland. In this setting, there is usually minimal, if any, evidence of parenchymal injury. **Therapy for prerenal azotemia is directed at optimizing volume status with isotonic fluids. In patients with the edematous disorders who have prerenal azotemia, special efforts are directed toward treating the underlying disease states (i.e., heart failure, cirrhosis) and optimizing systemic hemodynamics and renal perfusion.**

The hepatorenal syndrome (HRS) represents a unique, severe form of prerenal azotemia. HRS refers to the development of AKI in the patient with advanced hepatic disease, often resulting from

cirrhosis but also seen with metastatic tumor or alcoholic hepatitis. The reduction in renal perfusion appears to relate to a relative splanchnic vasodilatation that may be mediated via nitric oxide (NO), which is the endothelium-derived relaxing factor (Martin et al, 1998; Gines and Arroyo, 1999). HRS is characterized by oliguria, a benign urinalysis, urinary sodium avidity, and a progressive rise in serum creatinine (Cardenas, 2005). HRS is a prerenal disease because the kidneys are normal histologically and have been successfully used in renal transplantation (Koppel et al, 1969). The diagnosis is one of exclusion; after ATN, acute glomerulonephritis (AGN), vasculitis, or correctable forms of reduced renal perfusion have been excluded. Thus the diagnosis of HRS requires a lack of improvement in renal function following discontinuation of potential nephrotoxins and a trial of fluid repletion. The best hope for reversal of HRS is an improvement in hepatic function or a successful liver transplantation (Gonwa et al, 1991; Cardenas, 2005); however, not all cases of HRS will resolve with this approach (Pham et al, 2005). The use of simultaneous liver-kidney transplantation is evolving (Nadim et al, 2012). It is difficult to predict the cases of HRS that will regain renal function spontaneously with liver transplant alone versus those that exhibit irreversible renal injury and would also benefit from a kidney transplant. Protracted HRS may lead to irreversible loss of kidney function. Combination therapy with midodrine (a selective α_1 -adrenergic agonist) and octreotide (a somatostatin analogue) has been shown in a few small clinical trials to improve renal function and short-term survival (Angeli et al, 1999; Esrailian et al, 2007; Skagen et al, 2009). Terlipressin, a vasopressin analogue available in Europe, improves renal function in HRS; however, evidence regarding mortality is equivocal (Gluud et al, 2012). Nevertheless, the overall impact of medical therapy for HRS has been minimal and the outlook for HRS without liver transplantation appears bleak. The role of hemodialysis (HD) support appears to be limited to those HRS patients awaiting liver transplantation or resolution of their primary hepatic disease, because survival is generally limited by the severity of liver failure. HD is often difficult in HRS because of hemodynamic instability.

Postrenal Azotemia

Obstruction of the urinary tract may cause AKI. To be the cause of AKI, urinary tract obstruction must involve the outflow tract of both kidneys, unless preexisting renal dysfunction is present, in which case the obstruction may involve only a single kidney. Patients with acute urinary tract obstruction may present with hematuria, flank or abdominal pain, or signs of uremia. A high index of suspicion for urinary tract obstruction should exist for patients with previous abdominal or pelvic surgery, neoplasia, or radiation therapy. Although oligoanuria suggests complete obstruction, partial obstruction may exist in the presence of adequate urinary output. Oligoanuria is a powerful diagnostic clue that suggests a differential diagnosis of urinary tract obstruction, severe ATN with cortical necrosis, or bilateral vascular occlusion. Lesions that may cause obstruction can be either intrinsic or extrinsic to the genitourinary tract. If urinary tract obstruction is a diagnostic consideration, renal ultrasonography is sensitive and specific (90% to 95%) in confirming the diagnosis of hydronephrosis. This test may be operator dependent, so the experience of the radiologist is crucial. False-negative tests may be seen with periureteral metastatic disease or retroperitoneal fibrosis (Somerville et al, 1992). Renal radionuclide studies or retrograde pyelography may be helpful in this circumstance. If urinary tract obstruction is a diagnostic consideration, renal ultrasonography should be performed because obstruction represents a potentially reversible cause of AKI.

Although urologists are familiar with the various primary pathologies responsible for obstruction, iatrogenic causes should additionally be considered. Any drainage device such as a urethral catheter or ureteral stent should be assessed for patency. Hemorrhage and lymphocele are uncommon sequelae of surgery, but they can result in AKI by causing extrinsic compression. Urinary extravasation or fistula formation is a complication of urinary tract reconstruction or injury. This can cause a rise in the

BUN and serum creatinine as a result of reabsorption but preservation of actual GFR. Diagnosis of urinary extravasation requires analysis of fluid from the area near the reconstructed site. The drain creatinine is compared with the serum creatinine levels. Ratios of 10:1 are virtually diagnostic for extravasation; however, smaller ratios may be observed when the urine has been diluted by other serous fluids. Other ways to confirm urinary extravasation are by intravenous administration of a vital dye excreted by the kidneys (such as indigo carmine or methylene blue) or radiographic demonstration of a fistula (isotope renography, retrograde pyelogram, cystogram, computed tomography [CT]). This type of AKI resolves with drainage of the urinoma and definitive treatment of the urinary fistula. The reader is referred to other chapters in this text for more in-depth review of obstructive uropathy.

Intrinsic Renal Disease

The major causes of AKI resulting from intrinsic renal disease include AGN, AIN, and ATN. Because ATN is the most common cause of AKI in the hospitalized patient, special emphasis will be given to ATN.

Acute Glomerulonephritis

The presence of proteinuria, hematuria, and red blood cell (RBC) casts is highly suggestive of glomerulonephritis. The importance of the urinalysis in the evaluation of patients with AKI cannot be overemphasized, and the physician must develop skill and expertise in interpreting the microscopic findings. Such skills are critical in the recognition of AGN as the cause of AKI, because the diagnosis of AGN has a tremendous impact on disease management.

The combination of AGN (based on urinalysis findings) and a rapid loss of kidney function define the clinical syndrome of rapidly progressive glomerulonephritis (RPGN). The differential diagnosis and management of RPGN are beyond the scope of this chapter (Little and Pusey, 2004). A simplified differential diagnosis of RPGN is summarized in Box 46-2. It is crucial to appreciate the impact that urinary microscopic findings of AGN have on the aggressive evaluation and management of patients with this type of AKI. This usually includes a renal biopsy and detailed serologic evaluation for the presence of systemic vasculitis, collagen vascular disease, and an infectious process. RPGN comprises a group of glomerulonephritides that progress to renal failure in a matter of days to months in the presence of extensive extracapillary proliferation (i.e., crescent formation in a large percent of glomeruli). Patients with RPGN have been divided into three patterns defined by their immunologic pathogenesis: (1) type I: anti-glomerular basement membrane (anti-GBM) (e.g., Goodpasture); (2) type II: immune complex deposition disease (e.g., systemic lupus erythematosus [SLE], poststreptococcal glomerulonephritis); and (3) type III: pauci-immune (e.g., antineutrophil cytoplasmic autoantibody [ANCA]-positive disease such as granulomatosis with polyangiitis disease, formerly known as Wegener granulomatosis). Patients are categorized based on the results of the immunofluorescence of the renal biopsies and results of serologic testing for anti-GBM titer, ANCA, lupus serologies, and so on. Specific therapies (including parenteral steroids, cyclophosphamide or other cytotoxics, and possibly plasma exchange) tailored to the disease entity diagnosed may be lifesaving. Hence early recognition of RPGN based on urinalysis findings is critical.

Acute Interstitial Nephritis

The diagnosis of AKI secondary to AIN may be suggested by the urinalysis findings of sterile pyuria, white blood cell casts, and eosinophiluria (using Hansel stain) (Michel and Kelly, 1998). AIN is most often induced by drug therapy, although sarcoidosis, streptococcal, viral, or *Legionella* infections may also be responsible. The list of offending drugs associated with AIN is extensive, but the most

 Cimetidine, omeprazole
 Allopurinol
 Ciprofloxacin and perhaps other quinolones
 5-Aminosaliculates

common causes of AIN include those identified in [Box 46-3](#). The major histologic changes are interstitial edema and marked interstitial infiltrate of T lymphocytes and monocytes ([Laberke and Bohle, 1980](#)). Eosinophilic plasma cells and polymorphonuclear cells may also be detected. Granulomata formation, in the past thought to be particular to the renal disease of sarcoidosis, can occur in any form of AIN.

The clinical presentation, although variable, usually involves abnormal urine sediment (described earlier), fever, and a rising serum creatinine associated with the administration of the offending drug ([Nolan et al, 1986](#)). Skin rash is seen in about 25% of

cases. Eosinophilia and eosinophiluria is present in more than 75% of cases, with the exception of AIN resulting from NSAIDs, where fever, rash, and eosinophilia are typically absent. Proteinuria with most drugs is usually modest with less than 0.5 to 1 g/day. Proteinuria in the nephrotic range has been frequently seen with AIN of NSAIDs (especially fenoprofen) and in selected cases with ampicillin, rifampin, ranitidine, and interferon. It is speculated that increased glomerular capillary permeability is related to cytokine release of the infiltrating T cells ([Neilson, 1989](#)). The development of AIN is not dose dependent, and recurrence can occur with second exposures to the same or a related drug. The onset of AIN might occur from 3 to 5 days (especially second exposures) to several weeks after drug therapy.

The diagnosis is usually suspected in the AKI patient with characteristic urinary sediment abnormalities and a history of an offending drug therapy. Although the clinical picture may be highly suggestive of AIN, the diagnosis is confirmed only by renal biopsy. In a case series of patients with clinical diagnosis of AIN who had native kidney biopsies performed, urine eosinophils did not distinguish AIN from other causes of kidney disease such as ATN ([Muriithi et al, 2013](#)). When suspected, most clinicians will observe the response to withdrawing the offending agent with the expectation that renal function will begin to improve within 3 to 7 days ([Baker and Pusey, 2004](#)). No further evaluation or therapy is required if renal function improves. Lack of response, severe AKI, or uncertainty of diagnosis may be indications to proceed with a renal biopsy. There are no controlled clinical trials evaluating the efficacy of immunosuppressive therapy. There is some experimental and suggestive clinical evidence that steroid and/or cytotoxic therapy may be beneficial to hasten recovery of renal function and to reduce interstitial fibrosis.

ACUTE TUBULAR NECROSIS**Incidence and Etiology**

Overall, AKI may affect 2% to 7% of patients in a tertiary care hospital, and the incidence of AKI in the surgical or medical ICU may exceed 25% to 35%. The majority of all hospital-acquired AKI is secondary to ATN ([Myers and Moran, 1986](#); [Uchino et al, 2005](#)). Renal hypoperfusion and renal ischemia are the most common causes of ATN, although nephrotoxic insults from various agents are being recognized with increasing frequency. A detailed listing of both exogenous and endogenous nephrotoxic compounds is summarized in [Boxes 46-4](#) and [46-5](#).

Pigment Nephropathy/Rhabdomyolysis

Pigment nephropathy resulting from hemoglobin or myoglobin may be suspected in the appropriate clinical situation (post-traumatic or atraumatic after intoxications). In hemoglobinuria, there is a discrepancy between the finding of hematuria by dipstick and the absence of RBCs on urinary microscopy. In muscle breakdown caused by toxicity, trauma, surgical injury, or surgical positioning, the creatine phosphokinase (CPK) in blood is usually elevated and can be diagnostic for rhabdomyolysis. The combination of renal hypoperfusion and the nephrotoxic insult of myoglobin or hemoglobin within the proximal tubule can result in ATN.

In urology, two specific clinical circumstances have been identified in association with rhabdomyolysis. The first is protracted exaggerated lithotomy positioning, as used in urethral stricture surgery ([Anema et al, 2000](#); [Vijay et al, 2011](#)). Muscle groups of the buttocks (gluteals) are often affected. Significant rhabdomyolysis requiring gluteal fasciotomies has also been reported with robotic-assisted radical prostatectomy using lithotomy positioning ([Keene et al, 2010](#)). Long exposure to lithotomy positioning, greater than 5 hours, is the greatest risk factor. Attention to padding, positioning, and any maneuver that can reduce the duration of exaggerated positioning will help prevent this complication. The second situation is following laparoscopic donor

nephrectomy (Kuang et al, 2002; Troppmann and Perez, 2003; Reisiger et al, 2005; Deane et al, 2008) or laparoscopic nephrectomy (Glassman et al, 2007). The etiology in this circumstance has been ascribed to ischemia in the downside iliopsoas from prolonged lateral decubitus positioning. Identified risk factors include prolonged surgical time and high body mass index (Glassman et al, 2007). The clinical clues to rhabdomyolysis in the urologic setting relate to unusually severe muscle pain early in the postoperative setting combined with tea-colored urine. Patients may report downside low back pain for nephrectomy and buttock pain for lithotomy cases. Clinical suspicion is the most important feature for recognizing the diagnosis because the

condition is very uncommon. Rhabdomyolysis can be confirmed by an extremely elevated blood CPK. Early recognition of this disorder is crucial because a forced alkaline diuresis is indicated to minimize nephrotoxicity. Nonetheless, patients may require dialysis support and there is a possibility of nonrecovery of renal function.

Intrinsic/Extrinsic Toxic-Related Acute Tubular Necrosis

Similarly, the tumor lysis syndrome might be suspected in the appropriate clinical setting, when marked hyperuricemia/hyperuricosuria and crystalluria are recognized. A forced alkaline

diuresis may limit nephrotoxicity and is usually recommended prophylactically before an aggressive chemotherapy regimen.

The list of potential exogenous nephrotoxic agents is exhaustive (see Box 46-4). Simply stated, for a patient who develops ATN while receiving medications, each medication should be reviewed for the possibility of nephrotoxicity. The most commonly seen nephrotoxins in the hospitalized patient include radiographic contrast material, antibiotics (especially aminoglycosides and amphotericin B), chemotherapeutic agents, NSAIDs, and ACE-inhibitor drugs.

In the contemporary practice of hospital-based medicine, recognition of AKI in human immunodeficiency virus (HIV) patients deserves special comment. Patients with HIV infection may develop AKI as a result of the same causes as uninfected patients, but protease inhibitors have been associated with the development of AKI (Izzedine et al, 2009). Ritonavir and indinavir (as well as acyclovir, foscarnet, and sulfadiazine) have been associated with reversible AKI previously thought secondary to crystalluria and intrarenal obstruction (Olyaei et al, 2000). Historically, patients treated with indinavir developed renal colic because indinavir renal stones can be associated with urinary tract obstruction (Kohan et al, 1999). This drug is now infrequently used in contemporary practice. Newer antiretroviral agents may be toxic to the kidney, and newer forms of AKI related to AIN have been described (Izzedine et al, 2009).

Natural History

The oliguric phase usually begins less than 24 hours after the inciting incident and may last for 1 to 3 weeks. Urine volume averages 150 to 300 mL/day. The oliguric phase may be prolonged in the elderly. During this phase, the clinician must be alert for the expected complications, with special emphasis on metabolic consequences, gastrointestinal bleeding, and infection.

The diuretic phase is characterized by a progressive increase in urine volume, which is a harbinger of renal recovery. However, the SCr may continue to rise for another 24 to 48 hours before it reaches a plateau and falls. Severe polyuria during this phase is currently seen less frequently. Careful management during this phase is crucial because up to 25% of deaths with AKI may occur during this phase, usually related to fluid and electrolyte abnormalities as well as infection. Finally, the recovery phase ensues. Renal function returns to near baseline, but abnormalities of urinary concentration and dilution may persist for weeks or months.

Pathophysiology

Knowledge of the basic processes involved in the development of ATN is important to understanding contemporary therapies directed at limiting renal damage and promoting more rapid renal recovery (Fig. 46-1). In hospital practice, ischemic ATN is the most commonly encountered form of the disease. Therefore the following discussion focuses on ischemic renal injury.

A variety of biochemical changes occur during ischemia and reperfusion, and these changes are responsible for the cell dysfunction observed in ATN (Myers et al, 1984; Myers and Moran, 1986). Deranged microcirculation and amplified vasoconstriction are early manifestations following hemodynamic alterations, which are shortly followed by inflammatory response (Bonventre and Yang, 2011). The sentinel biochemical event in renal ischemia, however, is the depletion of adenosine triphosphate (ATP), which is the major energy currency for cellular work. ATP is metabolized to adenosine monophosphate (AMP). During prolonged oxygen deprivation, AMP is further metabolized to the nucleosides adenosine, inosine, and hypoxanthine. These compounds diffuse from the cell, resulting in the loss of the substrate reservoir for ATP synthesis after reperfusion (Sharfuddin and Molitoris, 2011). Furthermore, hypoxanthine becomes an important substrate in the development of oxygen free radicals during the reperfusion period. Provision of exogenous adenine and inosine decreases cellular injury in experimental renal ischemia (Siegel et al, 1980).

ATP depletion results in impaired function of the plasma membrane and intracellular ATPases that are vital to normal cell function. As a consequence of impairment of the Na⁺/K⁺-ATPase, cytosolic concentrations of Na⁺ and K⁺ are altered and cell swelling results (Alejandro et al, 1995). Dysfunction of the plasma membrane Na⁺/Ca²⁺-ATPase and intracellular Ca²⁺-ATPase leads to high intracellular levels of Ca²⁺. The increase in intracellular Ca²⁺ has been associated with multiple aspects of renal cell injury including disruption of the cytoskeleton, activation of Ca²⁺-dependent phospholipases, acceleration of the conversion of xanthine dehydrogenase to xanthine oxidase (potentiating reperfusion injury), and uncoupling oxidative phosphorylation. The activation of phospholipases results in damage to the lipid bilayer, which is critical to the normal function of the plasma membrane and intracellular organelles such as mitochondria. Phospholipase activation leads to an accumulation of free fatty acids and lysophospholipids, which are detrimental to vital cellular function, although the mechanism of such action is not clear.

Oxidative stress during reperfusion after ischemia is associated with cellular damage. Recall that ATP is metabolized to hypoxanthine. High levels of intracellular Ca²⁺ activate a calmodulin-dependent protease that converts xanthine dehydrogenase to xanthine oxidase. The conversion of hypoxanthine to xanthine during reperfusion is the major source of superoxide. This is ultimately metabolized to OH⁻, which causes cell damage. Finally, the protease calpain is activated and contributes to ischemic renal injury (Edelstein et al, 1997). Calpain regulates membrane channels, kinase activation, and interactions between cytoskeletal proteins.

As the name suggests, ischemic ATN is characterized by renal tubular cell injury. This may be sublethal or lethal. Because obvious necrosis is not a cardinal histopathologic finding in ATN (Racusen et al, 1991), sublethal injury is important. During normal function of the kidney, the medulla operates at the brink of hypoxia because of the countercurrent diffusion of oxygen from the descending to ascending vasa rectae. During prolonged ischemia, medullary hypoxia intensifies and the high metabolic requirement of the nephron structures located in the outer medulla is most sensitive to injury. The S3 portion of the proximal tubule sustains the most severe injury (Witzgall et al, 1994). Other structures that sustain injury in this region include the medullary thick ascending limb (mTAL), which is metabolically active and rich in the energy that requires Na⁺/K⁺-ATPase.

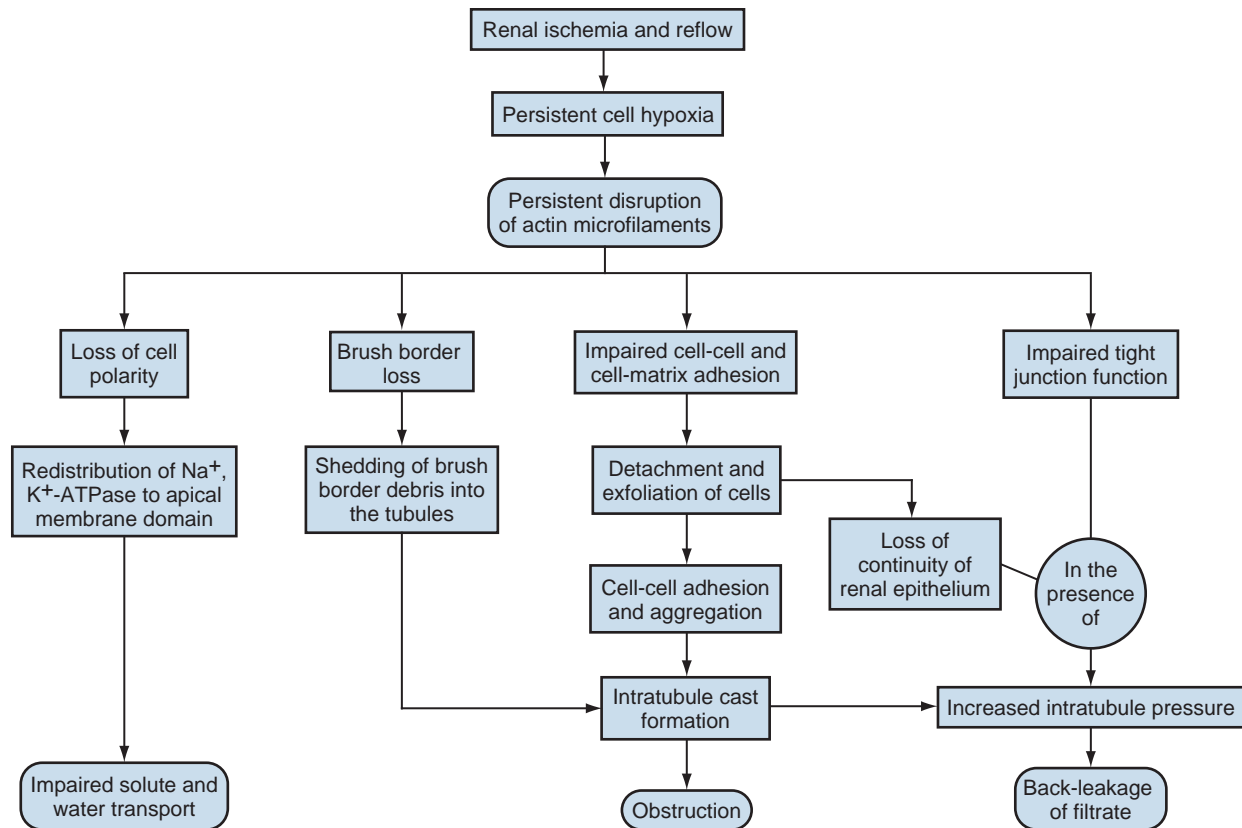

Figure 46-1. Pathophysiology of ischemic acute renal failure. The profound reduction in glomerular filtration rate associated with renal ischemia is a result of a combination of intrarenal hemodynamic alterations and tubular epithelial injury leading to tubular obstruction and back-leakage of glomerular ultrafiltrate. ATPase, adenosine triphosphatase. (From Brady HR, Brenner BM, Lieberthal W. Acute renal failure. In: Brenner BM, editor. *Brenner & Rector's the kidney*. Philadelphia: Saunders; 1996. p. 1200–52.)

Sublethal injury to tubular cells leads to aberrations in the cytoskeletal organization of the tubule cells (Molitoris, 1991; Sharfuddin and Molitoris, 2011). This is manifested as a loss in the cell polarity. The brush border disappears, and there is redistribution of the basolateral Na^+/K^+ -ATPase and integrins (Lieberthal, 1998). As a result, the normal unidirectional transport of salt and water across tubular cells is disrupted, and the ability of the renal epithelium to act as a barrier to the free movement of solute and water is lost. The loss of the tight junctions permits backleak of glomerular filtrate, which has been one of the well-established pathophysiologic features of ATN (see Fig. 46-1). In addition to the loss of tight junctions, there is a loss in cell-matrix adhesion (Gailit and Clark, 1993). The redistribution of the integrins disrupts the normal cell adherence to the tubular basement membrane. As a result, abnormal cell-cell adherence develops and contributes to tubular obstruction.

Following sublethal injury, the kidney has a remarkable capacity for repair of normal structure and function. The study of renal recovery from ATN is a relatively new concept with great potential for clinical application. Increased mitotic activity and epithelial regeneration are notable features of ATN (Thadhani et al, 1996). Certain aspects of renal recovery duplicate events in renal development (Witzgall et al, 1994). A number of growth factors play a role in recovery. Epidermal growth factor, insulin-like growth factor-1 (IGF-1), and hepatocyte growth factor have been demonstrated to limit renal injury and accelerate renal recovery in experimental ischemic ATN (Thadhani et al, 1996).

In ischemic ATN, RBF is reduced by 50% or more, and the perfusion defect is most marked in the outer medulla. The two predominant reasons for this include vasoconstriction and congestion of the medullary vasculature by leukocytes, red cells, and platelets.

Ischemic renal injury is marked by intrarenal vasoconstriction as a result of endothelial cell injury. Vasoconstriction results from the imbalance between endothelin (ET) and endothelial-derived nitric oxide (EDNO) (Lieberthal, 1998). ET receptor blockers have been shown to ameliorate ischemic renal damage and improve renal function (Lieberthal, 1998). The endothelial injury sustained in ATN also leads to decreased production of EDNO by constitutive NO synthase. The decreased EDNO leads directly to vasoconstriction but also permits increased ET production (Lieberthal, 1998).

The persistent hemodynamic abnormalities in ATN are also maintained by congestion of the medullary vasculature. Current evidence suggests that ischemic injury results in the release of inflammatory mediators that activate adhesion molecules on leukocytes and upregulates their receptors on the endothelium (Sharfuddin and Molitoris, 2011). Antibodies directed at leukocyte adhesion molecules or their endothelial ligands (i.e., intercellular adhesion molecule-1 [ICAM-1]) ameliorate ischemic renal injury (Kelly et al, 1996; Dragun and Haller, 1999). Neutrophils play an important part in the injury cascade. In models where the effects of neutrophils are eliminated by delivering antibodies to certain chemokines, injury is ameliorated (Miura et al, 2001). Interestingly, the tubular epithelium plays an active role in this inflammatory response by generating chemokines that potentiate recruitment of inflammatory cells (Bonventre and Zuk, 2004). These include monocyte chemoattractant protein-1 (MCP-1), interleukin-8 (IL-8), RANTES (regulated-on activation, normal T cells expressed and secreted), and epithelial neutrophil-activating protein 78. In addition to the role of neutrophils, there is evolving evidence that lymphocytes are important in the ischemia/reperfusion injury paradigm. Knockout mice lacking $\text{CD4}^+/\text{CD8}^+$ cell adhesion receptors

on T lymphocytes are protected from ischemic injury (Rabb et al, 2000). Also, costimulatory blockade can ameliorate ischemic injury (Takada et al, 1997). Newer agents are being developed to handle the early inflammatory events in renal ischemia, which may bear practical application, particularly in the setting of renal transplantation.

CLINICAL APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ACUTE KIDNEY INJURY

General

Distinguishing among prerenal, intrinsic renal, and postrenal causes of AKI may prove to be a challenging clinical exercise (Fig. 46-2). A thorough history and physical examination to assess volume status, cardiovascular hemodynamics, potential nephrotoxic insults, and evidence of systemic disease should be undertaken in AKI patients. All interventions and drug therapies surrounding an AKI event should be outlined against the timeline of changes in renal function. Electronic medical records can now help facilitate this task (Goldstein et al, 2013). It is also critical to know the level of preexisting renal function. One should identify the presence of risk factors known to be associated with AKI such as advanced age; comorbid conditions (heart failure, liver failure, renal insufficiency, diabetes); radiocontrast exposure; therapy with aminoglycoside antibiotics, NSAIDs, or ACE inhibitors; and atheroembolism. In perioperative AKI, the nature and magnitude of the procedure (open vs. endoscopic), blood loss, hemodynamic stability, integrity of the urinary tract, and intraoperative drug treatment are critical intraoperative issues to identify.

On examination, the vital signs and hemodynamic parameters should be critically assessed. Hypotension, particularly orthostatic hypotension, suggests volume depletion and prerenal AKI. Hypertension with advanced renal insufficiency can be an indicator of volume overload, suggesting the need for diuretics or dialysis. A patient's weight is helpful information, and its daily measurement is important in the diagnosis and management of AKI. After major urologic procedures (e.g., cystectomy, nephrectomy, transplantation), measurement of the central venous pressure or pulmonary artery wedge pressure may provide an estimate of volume status.

Examination of the urinalysis results is fundamental to the evaluation of the patient with AKI (Perazella and Parikh, 2009). The simple urinalysis may distinguish the cause of AKI among the various possibilities. Table 46-2 highlights the various urinary abnormalities associated with the clinical diagnoses. For example, proteinuria, hematuria, and RBC casts are pathognomonic of glomerulonephritis. The classic sediment of ATN includes pigmented (muddy brown) granular casts and renal tubular epithelial cells, which may be seen in nearly 80% of cases of oliguric AKI.

Determination of urinary chemistry may be helpful in determining the cause of the AKI. The urine sodium, creatinine, and osmolality should be measured. The fractional excretion of sodium or the renal failure index should be calculated (Fig. 46-3). Note that a low fractional excretion of sodium (or renal failure index) may be associated with either prerenal azotemia or AGN (Table 46-3). These entities can be separated clinically by examination of the urinalysis results. Conditions associated with prerenal azotemia have bland urinalysis results, whereas proteinuria, RBCs, and RBC casts are seen with AGN. Other causes of AKI associated with a low fractional excretion of sodium include HRS and selected types of ATN such as that resulting from iodinated contrast material, rhabdomyolysis, sepsis, and multisystem organ failure. Both ATN and

obstruction may have an increased fractional excretion of sodium. Here again, the urinalysis is crucial in sorting out the differential diagnosis. ATN includes classic sediment with pigmented, coarsely granular casts, but the urinalysis results seen in obstruction are often bland with or without microhematuria.

The urine output might be a clue to the diagnosis of AKI. The presence of marked oligoanuria suggests urinary tract obstruction, renovascular occlusion, or cortical necrosis. In contrast, nonoliguric AKI is being recognized with increasing frequency, and careful monitoring of serum creatinine in at-risk patients is of paramount importance.

Renal Vein Thrombosis

Renal vein thrombosis represents an uncommon cause for AKI. Certain renal diseases are associated with increased thrombosis. These include a variety of the proteinuric glomerulonephritides, especially with nephrotic range proteinuria (Barbano et al, 2013). A common disease in this category is membranous glomerulonephritis (MGN). Other causes for renal vein thrombosis that urologists would see in practice include renal cell cancer-related tumor thrombus, postoperative thrombosis related to manipulation of the renal circulation (partial nephrectomy), and renal transplantation. There are no systematic reviews of treatment for renal vein thrombosis. In medical renal disease, anticoagulation is usually prudent when thrombosis is discovered, followed by an evaluation for other thrombophilic conditions. When renal vein thrombosis threatens renal function, thrombolytic therapy has been used (Barbano et al, 2013). This technique has been extended to the renal transplant circumstance as well (Fulton

et al, 2011). For renal cancer, nephrectomy with removal of the tumor thrombus is usually the therapy of choice.

Imaging

A variety of imaging modalities show clinical usefulness in the evaluation of AKI. The most widely used is renal ultrasonography. This noninvasive and readily available study is fairly sensitive for the identification of hydronephrosis. Duplex ultrasonography of the renal artery is useful for the identification of RAS or thrombosis (Carman et al, 2001). The absence of a Doppler signal from the artery is a noninvasive examination to confirm renal artery thrombosis.

Another useful imaging study in AKI is the abdominal plain radiograph to identify the presence of renal calculi, the location of renal calculi, or both. Additionally, the abdominal plain radiograph is particularly helpful to discern the proper position of the stents and drains. The radionuclide renal scan is a useful imaging study in selected clinical circumstances. Tc99m-mercaptoacetyltriglycine (MAG3) is a more useful imaging study in renal insufficiency than Tc99m-diethylenetriaminepentaacetic acid (DTPA) and is able to evaluate both renal flow and function (Taylor, 1999). The renal scan is a simple means for evaluation of renal flow in situations where renal artery thrombosis is a serious consideration such as after partial nephrectomy or renal transplantation. It is especially useful when there is renal insufficiency that prohibits the use of iodinated contrast (Jafri et al, 1988). Urinary extravasation can also be assessed by isotope renography.

Radiocontrast studies (intravenous pyelography [IVP], CT, angiography) are of limited value during AKI because of their ability to worsen renal insufficiency. Angiography is used to confirm renal artery thrombosis, stenosis, or dissection. Contrast studies such as CT urography or IVP yield poor-quality images in azotemic patients because of the inability to excrete contrast adequately. Notwithstanding, radiocontrast studies are frequently performed just proximal to surgery and may contribute in this manner to perioperative AKI.

MANAGEMENT OF ACUTE KIDNEY INJURY

Management of AKI is based on its cause (Alkhunaizi and Schrier, 1996; DuBose et al, 1997). When AKI is identified as prerenal, correction of the precipitating factors and restoration of renal perfusion usually lead to its resolution. Nephrotoxic drugs should be eliminated when clinically appropriate. Maintaining normal volume status is essential. In the postoperative setting, this implies judicious replacement of crystalloid, colloid, and blood, with close monitoring of the central venous pressure. The management of postrenal AKI will depend on its etiology. Any obstruction needs appropriate drainage, and urinary extravasation needs to be controlled.

The management of ATN focuses on the prevention of complications and providing an environment that is conducive to renal recovery (Box 46-6). Early consultation with a nephrologist improves the outcome of patients with AKI. Delay in consultation was associated with higher mortality, longer ICU length of stay, and increased number of systems failing at the time of consultation (Mehta et al, 2002a). During the initial evaluation, it is imperative to search for reversible causes such as volume depletion, obstruction, and vascular occlusion. During the initial stages, a trial of parenteral hydration with isotonic fluids may correct AKI secondary to prerenal causes (Prowle et al, 2014). Thereafter, fluid status should be monitored vigilantly to maintain euvolemia. In a patient with oliguria, special attention must be provided to avoid excessive hydration and volume overload, which might precipitate the need for dialysis (Godin et al, 2013; Nadeau-Fredette and Bouchard, 2013). Certain volume expanders such as hydroxyethyl starch have been associated with adverse renal effects (Mutter et al, 2013).

Consideration may be given to using pharmacologic intervention to convert the patient from an oliguric to nonoliguric state. In

general, increases in urinary volume make it easier to address problems of volume overload, hyperkalemia, and metabolic acidosis. Increases in urine volume may also provide room for supplemental TPN in the critically ill patient. Historically, the morbidity, need for dialysis, and mortality was considered lower in the de novo nonoliguric form of ATN; however, more recent data challenge this notion (Liangos et al, 2005).

Pharmacologic Intervention

Pharmacologic intervention to convert oliguric ATN to nonoliguric ATN is a salutary goal for the reasons noted earlier (Townsend and Bagshaw, 2008). Experimental studies on the use of diuretics, dopamine, atrial natriuretic peptide (ANP), and calcium channel blockers (CCBs) that attempt to convert oliguria to nonoliguric AKI have been performed. The applicability of these experimental studies to patients with AKI remains unproved.

Uncontrolled studies suggest that patients who respond to mannitol, furosemide, or dopamine with an increased urine output have better outcomes than nonresponders (Cosentino, 1995). The responders may simply have had less severe disease from the outset. Although de novo nonoliguric AKI has been associated with a lower mortality rate, there is little evidence that conversion from an oliguric to a nonoliguric state decreased the mortality rate. For the patients with established ATN, therapy with loop diuretics may increase urine output but has little effect on the severity or duration of the AKI (Cosentino et al, 1994).

Both loop diuretics and mannitol administration were proved to minimize the degree of renal injury if given at the time of the ischemic insult (Hanley and Davidson, 1981; Schrier et al, 1984; Cosentino, 1995). This is not the same as using these diuretics for the treatment of established ATN. Both diuretics are capable of inducing a diuresis to wash out obstructive debris and casts. Loop diuretics (e.g., ethacrynic acid, furosemide, and bumetanide) exert their pharmacologic effect in the loop of Henle, causing a large solute diuresis. Additionally, they decrease active NaCl transport in the thick ascending limb of Henle and thereby limit energy requirements in the metabolically active segment, which often bears significant ischemic insult. There are several theoretic reasons that loop diuretics may be of benefit in AKI. Loop diuretics might protect cells of the ascending limb of Henle from hypoxic damage, might increase tubular flow to prevent intratubular obstruction, might inhibit tubuloglomerular feedback to maintain a favorable GFR, and might increase RBF by decreasing renal vascular resistance. The available clinical data do not support an improved outcome in patients who respond to loop diuretics (Shilliday and Allison, 1994; Shilliday et al, 1997). A prospective, randomized placebo-controlled study examining the effect of loop diuretics on renal recovery, dialysis, and death in patients with AKI showed no effect (Shilliday et al, 1997). Observational data suggested that diuretic use in critically ill patients with AKI is associated with an increased mortality rate using multivariate analysis and propensity scores (Mehta et al, 2002b). A prospective, multicenter, epidemiologic study showed that the use of loop diuretics was not associated with higher mortality (Uchino et al, 2004). Given these mixed results, it is reasonable to administer a trial of a loop diuretic in escalating doses, and if the patient does not respond, the drug should not be readministered because large doses of loop diuretics may be ototoxic and the large infusion volume may cause pulmonary edema (Nadeau-Fredette and Bouchard, 2013).

Mannitol, an osmotic diuretic, theoretically ameliorates AKI by flushing intratubular casts, increasing RBF, increasing urine flow, reducing hypoxic cell swelling, protecting mitochondrial function, and scavenging free radicals. Mannitol use continues to be promoted prophylactically in certain high-risk patient groups because of its demonstrated benefit in animal models of AKI (Burke et al, 1983; Schrier et al, 1984). Mannitol has shown some benefit in the clinical setting of AKI (Novick, 1983; Weimar et al, 1983; Simmons et al, 2008), particularly when administered prophylactically or within a short time after an ischemic or nephrotoxic insult. The best clinical example of this is its administration before renal artery clamping during partial nephrectomy or during renal transplant (Yang et al, 2014). However, other studies in humans failed to demonstrate the effectiveness of mannitol in the prevention or treatment of ischemic or toxic AKI (Burke et al, 1983; Shilliday and Allison, 1994; Yang et al, 2014).

Dopamine includes selective renal vasodilator properties that cause natriuresis and increased urine output. Low-dose "renal-dose" dopamine (0.4 to 2.0 µg/kg/min) activates dopamine-1 receptors, which induce renal vasodilation and increased RBF. An objective review of controlled studies demonstrates that these benefits remain speculative (Denton et al, 1996; Lassnigg et al, 2000). In a randomized trial of 328 critically ill patients with AKI assigned to continuous infusion of placebo or low-dose dopamine (2 µg/kg/min), peak serum creatinine concentration, requirement for dialysis, length of hospital stay, and mortality rate did not differ between the two groups (Bellomo et al, 2000). Also, prophylactic

use of low-dose dopamine in patients undergoing coronary artery bypass surgery has not proved effective in preventing the development of renal impairment in these patients (Woo et al, 2002). It is also important to note that the use of dopamine has been associated with serious cardiac, vascular, and metabolic complications in the critically ill, and therefore dopamine should be used cautiously.

Fenoldopam is a selective dopamine-1 receptor agonist (DA-1) that causes DA-1 receptor-mediated vasodilation and does not stimulate DA-2 or α - or β -adrenergic receptors. Fenoldopam reduces renal vascular resistance and increases RBF and fractional excretion of sodium and free water clearance in studies of normal volunteers and hypertensive patients (Mathur et al, 1999). A few studies in animal models (Singer and Epstein, 1998; Halpenny et al, 2001) are consistent with the notion that DA-1 agonists may be useful in preventing or treating AKI. A multicenter trial, however, did not show any protective benefit of the selective dopamine-1 agonist (fenoldopam mesylate) in the prevention of contrast-induced renal dysfunction in an at-risk population (Landoni et al, 2007). A randomized prospective study of fenoldopam in patients undergoing partial nephrectomy in a solitary kidney also failed to show a renal functional benefit (O'Hara et al, 2013).

In some animal studies, the effects of ischemic AKI could be reversed with the use of an intrarenal arterial infusion of atrial natriuretic peptide (ANP) (Nakamoto et al, 1987; Shaw et al, 1987), but other experimental studies have been contradictory. The proposed mechanism by which this occurs is the vasodilatory action of ANP. In experimental models of established ATN, the combination of ANP with dopamine to prevent systemic hypotension resulted in a rise in GFR induced by arteriolar vasodilatation. The treated animals also exhibited less tubular necrosis and fewer casts, suggesting tubular recovery was promoted. The efficacy of ANP in established ATN in humans has been evaluated in two trials (Rahman et al, 1994; Stevens et al, 2007). The first was a small, randomized trial suggesting a benefit of ANP therapy. A larger prospective, multicenter, randomized study with ANP in patients with ATN (oliguric and nonoliguric) showed no benefit on morbidity or mortality with ANP (Lewis et al, 2000). However, in a subset of patients with oliguric ATN, clinical improvement was seen with ANP infusion. Another study in a select population did not demonstrate benefit (Lewis et al, 2000).

CCBs inhibit voltage-gated calcium entry into cells and are reported to reverse vascular constriction, to increase GFR, and to improve renal plasma flow (Epstein, 1993). A few limited animal studies in experimental AKI generally support a protective benefit of CCBs. The clinical benefit of CCBs most widely studied has been the effect on graft function in renal transplant recipients (Alkhunaizi and Schrier, 1996).

In summary, review of the data regarding pharmacologic intervention for established ATN supports a trial of isotonic fluid repletion (Prowle et al, 2014). Judicious use of intravenous loop diuretics may increase urine output, but their ability to have an impact on improved patient survival in AKI is still unproven. Similarly, the clinical data on "renal-dose" dopamine are scant and do not support its widespread use in established ATN. If a trial of dopamine is considered, it should be limited to a 24- to 48-hour infusion.

Conservative Management

After the clinical diagnosis of ATN is made, conservative medical management is in order (Box 46-7). This would include attempts to minimize further renal parenchymal injury, to ensure provision of nutrition, to maintain the metabolic balance, and to promote recovery of renal function.

Optimizing the patient's volume status is imperative, particularly in patients with oliguric AKI (DiBona, 1994; Godin et al, 2013; Prowle et al, 2014). If such patients are provided with large volumes of intravenous (IV) fluid or are allowed free access to oral fluids, they are at risk for developing fluid overload or hyponatremia. In the oliguric patient, fluids should be restricted to total

Protein (1.0-1.8 g/kg/day) and maintain caloric intake; consider forms of nutritional support
Carbohydrate intake at least 100 g/day to minimize ketosis and endogenous protein
Catabolism

DRUGS

Review all medications
Stop magnesium-containing medications
Adjust dosage for renal failure; readjust with improvement of glomerular filtration rate

output plus insensible losses. If required, pharmacologic intervention with loop diuretics may promote increases in urinary volume.

Providing adequate nutrition is important for the recovery of the critically ill patient with AKI (Fiaccadori et al, 2008). Preexisting or hospital-acquired malnutrition is an important factor contributing to the high mortality seen in patients with AKI (Druml, 1992). AKI not only affects water, electrolyte, and acid-base metabolism but also induces specific alterations in protein and amino acid, carbohydrate, and lipid metabolism (Druml, 1998). The metabolic alterations in AKI patients are determined not only by acute loss of renal function but also by the underlying disease process (i.e., sepsis, trauma, or multiple organ failure) and by the type and intensity of renal replacement therapy (RRT) (Druml, 2005).

The hallmark of metabolic alterations in AKI is activation of protein catabolism with excessive release of amino acids from skeletal muscle and sustained negative nitrogen balance (Druml, 1998; Price et al, 1998). Hepatic extraction of amino acids from the circulation, gluconeogenesis, and ureagenesis are all increased. Several additional catabolic factors (secretion of catabolic hormones, hyperparathyroidism, suppression and decreased sensitivities to growth factors, and release of inflammatory mediators) are operative in AKI. All of these factors mediate protein breakdown (Cianciaruso et al, 1991).

Frequently, AKI is associated with hyperglycemia caused by insulin resistance (Klouché and Beraud, 1998). When plasma insulin concentration is elevated, maximal insulin-stimulating glucose uptake by skeletal muscle is decreased by 50%. AKI is also associated with accelerated hepatic gluconeogenesis, mainly from conversion of amino acids released during protein catabolism, which cannot be suppressed by exogenous glucose infusions (Druml, 1992). The triglyceride content of plasma lipoprotein is increased in AKI, whereas total cholesterol and high-density lipoprotein (HDL) cholesterol are decreased (Schneeweiss et al, 1990). The major cause of lipid abnormalities in AKI is impairment of lipolysis. Renal replacement therapies themselves may present significant metabolic and nutritional consequences.

Appropriate nutritional therapy in patients with AKI may be beneficial in promoting recovery (Fiacadori et al, 2008). Caloric intake should be maintained, and carbohydrate intake should be at least 100 g/day to minimize ketosis and endogenous protein catabolism. A moderate protein intake of about 1 to 1.8 g/kg by weight per day may be required to maintain positive nitrogen balance. Higher protein intakes of up to 2.5 g/kg/day have been necessary to improve nitrogen balance in critically ill AKI patients on continuous dialysis, although no survival advantage was noted. Hence it should be stressed that a low-protein intake (<0.5 g/kg/day) may be unnecessary, and protein intake should not be severely restricted in AKI to limit the need for dialysis. In terms of types of amino acids used, diet or solutions including both essential and nonessential amino acids in standard proportions are recommended. Dietary phosphorus, potassium, and sodium chloride may be restricted. In the critically ill patient, nutritional support via TPN or enteral feedings should be considered. Previous studies demonstrate that the provision of adequate nutrition to the AKI population might improve survival (Chertow et al, 2000). Patients with AKI are candidates for the development of significant electrolyte abnormalities such as hyperkalemia, metabolic acidosis, hyperphosphatemia, and hypocalcemia. The prophylactic institution of a low-potassium diet accompanied by fluid restriction and oral phosphate binders may minimize these problems.

Hyperkalemia is the most common and most dangerous electrolyte abnormality in the AKI setting (Hoorn et al, 2013; Fordjour et al, 2014). If serum potassium exceeds 6 mEq/L, an electrocardiogram (ECG) should be performed with subsequent therapy based on the ECG findings. With hyperkalemia, the earliest changes demonstrate peaked T waves with subsequent broadening of the PR interval and eventual QRS broadening, which may mature into a sine wave form. The stages of therapy for acute hyperkalemia with ECG changes include (1) stabilizing the electrical membrane of the cardiac conduction system, (2) shifting potassium back intracellularly, and (3) eventual elimination of potassium from the body. Stabilizing the membrane of the cardiac conduction system may be accomplished with IV calcium salts, which have an immediate effect and a rather short duration of action. Shifting potassium into cells may be accomplished by a combination of IV glucose and insulin or IV sodium bicarbonate. Elimination of potassium from the body in a patient with AKI may be accomplished via the gastrointestinal tract with a cationic-binding resin. One study questions the efficacy of sodium polystyrene sulfate (commonly known as Kayexalate) and identifies an underappreciated risk associated with its use, which is colonic necrosis (Sterns et al, 2010). If severe hyperkalemia exists, dialysis may be required.

Dialytic Interventions

General

Despite adequate medical therapy, dialysis may be required for patients with severe AKI. The indications for the initiation of dialysis include volume overload, severe hyperkalemia, severe metabolic acidosis, pericarditis, selected poisonings, certain drug overdoses, and uremic symptomatology.

One or more of the specific indications usually precipitates the initiation of dialysis for patients with AKI. There is still debate on whether patient morbidity and mortality might be improved by early initiation of RRT; well-conducted randomized trials are lacking. Intensive dialysis, on the other hand, compared to standard dialysis intensity did not improve survival in patients with AKI in two well-performed multicenter randomized trials (Network et al, 2008; ASTRAL Investigators et al, 2009). Nevertheless, patients with AKI should begin dialysis on detection of severe fluid or electrolyte abnormalities or uremic symptomatology that cannot be controlled with conservative or medical therapies. A theoretical concern exists that the dialysis treatment itself may present a detrimental impact on the course of AKI from ATN. Three potential mechanisms have been postulated: a fall in urine volume, dialysis-induced

hypotension, and complement activation resulting from the blood-dialysis membrane interaction. Removal of excess volume and urea may each contribute to the fall in urine volume. Whether this reduction includes an impact on the clinical recovery of ATN is speculative. Hypotension is a common complication of HD in patients with AKI. Because autoregulation is impaired in ATN, such patients may be particularly sensitive to renal hypoperfusion, perhaps because of vascular injury of the endothelium and its vasodilatory products such as prostacyclin and NO. As a result, recurrent ischemic injury is more likely to occur and possibly might delay the restoration of renal function. Complement activation during the blood-dialyzer interaction is a third possible mechanism for dialysis-induced renal injury. Animal models suggest that blood interaction with cuprophane membranes (but not more biocompatible membranes) can lead to neutrophilic infiltration into the kidney and can prolong the course of AKI.

Dialysis Prescription and Modality

The contribution of the type of RRTs to clinical outcomes in AKI remains unresolved. Several factors that are operative during RRT for AKI may affect clinical outcome. These include dialysis modality and dialyzer membrane characteristics. HD is the standard dialytic modality for hemodynamically stable patients with AKI. HD treatments may be stressful hemodynamically and may possibly be complicated by hypotension, hypoxia, bleeding related to anticoagulant administered (usually heparin), and dialysis dysequilibrium with its manifestations ranging from cramps and headaches to seizures and coma.

In the hemodynamically unstable patient, slow fluid and solute removal can be achieved with continuous renal replacement therapy (CRRT). In addition to being better tolerated hemodynamically, CRRT is also as efficient as conventional HD at removing solutes throughout the course of 24 to 48 hours. Although the clearance rates of some small solutes such as urea are slower, the rates are closer at 24 hours and more urea is removed during 48 hours with CRRT than with a single, intermittent run of standard HD.

Peritoneal dialysis (PD) permits the removal of solutes and fluid by use of the peritoneal membrane as the dialyzer. This process does not require access to the circulation and is generally less stressful hemodynamically than standard HD. For this procedure, the dialysate is instilled into the peritoneal space via a catheter that is percutaneously placed. Fluid is allowed to dwell for a time and is then removed, taking with it uremic solutes by diffusion, as well as accomplishing ultrafiltration of fluid from an osmotic pressure gradient induced by high concentrations of glucose in the dialysate. Small randomized clinical trials suggest that PD may be comparable to daily HD with regard to efficacy and clinical outcomes (Gabriel et al, 2008). Although it is not popular in the United States, this method remains an option in noncatabolic patients in which use of PD can maintain fluid and electrolyte homeostasis while preventing uremic symptomatology (Chionh et al, 2013).

Nephrologists caring for AKI patients may select a continuous or intermittent dialysis method. An analysis of nine published studies comparing CRRT to intermittent HD (IHD) in patients with AKI showed no significant difference in clinical outcomes between the two groups (Tonelli et al, 2002). A meta-analysis of 13 clinical trials, totaling 1400 patients, also observed no mortality difference between CRRT and IHD. However, after adjusting for severity of illness and study quality, mortality seemed to be lower in the CRRT group (Kellum et al, 2002). Similarly, a well-designed study of 80 critically ill patients with AKI showed no difference in survival or renal recovery between continuous venovenous hemodialysis and IHD groups (Augustine et al, 2004).

Dialysis membranes may be classified as cellulose-derived or non-cellulose-derived membranes. The non-cellulose-derived membranes are synthetic polymers and are generally more biocompatible but more expensive. A meta-analysis of clinical trials comparing biocompatible versus nonbiocompatible membranes

showed no difference in mortality between groups (Jaber et al, 2002). Given the profound morbidity of patients with AKI, if a survival advantage attributable to biocompatible membranes exists, at best it is small. Similarly, high-flux membranes have not demonstrated a survival benefit, recovery of renal function, or duration of dialysis (Ponikvar et al, 2001).

Prognosis of Acute Tubular Necrosis

The prognosis of ATN is dependent on the underlying primary disease that resulted in the AKI, as well as any complications that arise (e.g., infection, cardiovascular, gastrointestinal bleeding, central nervous system). The mortality rate for patients with ATN is consistently around 50% regardless of the study population (Biesenbach et al, 1992; Network et al, 2008). This pessimistic outlook has changed little in the past 4 decades, despite the advent of effective dialysis (Lewers et al, 1970; Di Tullio et al, 1996; Liano and Pascual, 1996; Uchino et al, 2005). Mortality rates remain high today despite effective control of uremia because of an older, sicker population with severe concomitant illnesses. Mortality rates have been quantified as high as 75% in several series in the ICU population. Higher mortality rates are seen in elderly patients, in patients with respiratory failure, with multiorgan failure, with preexisting chronic diseases, and with systemic hypotension (Obialo et al, 1999). In a prospective multicenter study of mortality with critically ill patients with ATN, the factors predictive of early mortality were male gender, oliguria, mechanical ventilation, acute myocardial infarction, cerebrovascular accident/seizure, and chronic immunosuppression (Parker et al, 1998). Leading causes of death include bronchopulmonary infections, sepsis, cardiovascular disease, and bleeding disorders. Of patients who survive ATN, nearly half will experience a complete recovery of renal function and a majority of the remainder has an incomplete recovery (Fig. 46-4) (Spurney et al, 1991). Only about 5% of all AKI patients require chronic maintenance dialysis.

A separate question is whether the development of AKI itself directly contributes to mortality. In a prospective study of 183 patients who developed AKI after IV contrast exposure, the in-hospital mortality rate was substantially higher in the AKI group (34% vs. 7%) than in a matched control (Levy et al, 1996). This effect persisted after the adjustment of other comorbid diseases. The development of AKI is also known to increase the morbidity of patients, to prolong hospitalizations, and to increase hospital costs.

Prevention of Acute Tubular Necrosis

Special attention should be focused on the prevention of AKI, because the management of ATN is primarily one of conservative care and support. Patients at high risk (i.e., patients with preexisting azotemia, the elderly, volume-depleted individuals, diabetic patients) warrant careful clinical consideration of the relative risks and benefits of diagnostic or therapeutic interventions that have potential for nephrotoxicity. This is especially true for at-risk patients

who might undergo cardiac catheterization or other diagnostic studies requiring iodinated contrast material. Several classic studies deserve comment.

A study by Solomon and colleagues (1994) confirmed that intravenous hydration with saline was critical in diminishing the nephrotoxic effects of coronary arteriography for patients with preexisting azotemia (Solomon et al, 1994). The addition of either a loop diuretic or mannitol did not improve outcome. Rudnick and colleagues (1995) published a prospective, randomized trial of nearly 1200 well-hydrated patients undergoing cardiac catheterization to examine the effects of the newer nonionic contrast material (Rudnick et al, 1995). Patients were stratified for the presence or absence of azotemia ($\text{SCr} \geq 1.5 \text{ mg/dL}$) or diabetes mellitus. In patients without azotemia (with or without diabetes mellitus), the incidence of contrast-induced renal dysfunction was low (i.e., <1% to 2%) with either the ionic or nonionic contrast material. Those with preexisting azotemia experienced a 50% reduction in contrast-associated renal dysfunction with the nonionic material. These data suggest that in azotemic patients who require cardiac angiography, a protocol of intravenous hydration and the use of a nonionic contrast material appear warranted. Moreover, a meta-analysis also demonstrated that the use of the newer iso-osmolar non-ionic agents would be of benefit when compared with hypo-osmolar agents, especially in subjects with preexisting kidney disease and diabetes (McCullough et al, 2006).

In addition to these maneuvers in high-risk patients, pretreatment with *N*-acetylcysteine (600 mg orally twice daily for 48 hours) has been shown to reduce the incidence of radiocontrast-induced nephropathy (Tepel et al, 2000). A meta-analysis of randomized clinical trials using *N*-acetylcysteine in patients with reduced renal function clearly showed risk reduction for acute radiocontrast injury (Alonso et al, 2004). Nonetheless, meta-analysis conducted separately of randomized controlled trials using *N*-acetylcysteine for the prevention of radiocontrast-induced nephropathy did not warrant a strong recommendation for its clinical use (Kshirsagar et al, 2004; O'Sullivan et al, 2013).

Several trials have compared the benefits of two hydration protocols in reducing radiocontrast-induced nephropathy. A trial involving 1620 patients undergoing coronary angioplasty demonstrated a benefit of isotonic hydration as superior to half-isotonic hydration in prevention of nephropathy (Mueller et al, 2002). A smaller, single-center prospective randomized trial showed the benefit of IV hydration with sodium bicarbonate rather than sodium chloride administered 1 hour before contrast exposure in the prophylaxis of contrast-induced renal dysfunction (Merten et al, 2004). The latter protocol includes the advantage of timing because it was initiated 1 hour before the anticipated contrast study, rather than requiring 48 hours of pretreatment with *N*-acetylcysteine. A multicenter trial did not show any protective benefit of the selective dopamine-1 agonist (fenoldopam mesylate) in the prevention of contrast-induced renal dysfunction in an at-risk population (Stone et al, 2003). Similarly, a meta-analysis did not report any compelling benefit for the use of theophylline, an adenosine antagonist, in the prevention of contrast-induced nephropathy (Bagshaw and Ghali, 2005). In the aggregate, the aforementioned recommendations for the azotemic patients who require radiocontrast procedures warrant a protocol of IV hydration with isotonic fluids (Weisbord et al, 2008) and the use of nonionic contrast material in the lowest dose possible (Perazella and Reilly, 2011). The use of sodium bicarbonate as an isotonic fluid may be beneficial. Treatment with *N*-acetylcysteine before the procedure carries little risk but it may not be an effective preventive strategy (O'Sullivan et al, 2013).

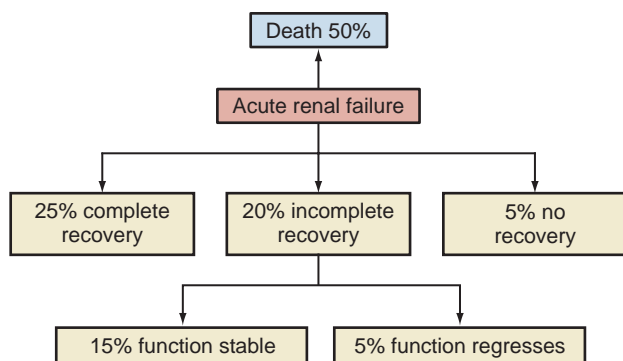

Figure 46-4. Prognosis of acute tubular necrosis.

CHRONIC KIDNEY DISEASE

The diagnosis of CKD implies a persistent abnormality in GFR with a wide spectrum of causes. The Workgroup of the U.S. National Kidney Foundation, Kidney Disease Outcomes Quality Initiative (K/DOQI) Advisory Board, recommended in 2002 that “chronic

KEY POINTS: ACUTE KIDNEY INJURY

- Creatinine as an assessment of renal function needs to be interpreted in the context of clinical events that are occurring in the patient.
- AKI is categorized based on pathophysiology as prerenal, postrenal, or intrinsic renal. The etiology and pathogenesis determine management. A new definition has recently been defined.
- Prerenal azotemia is transient renal hypoperfusion and responds well to isotonic fluid replacement.
- In considering postrenal causes of AKI, do not forget fistula and other iatrogenic causes.
- The inflammatory response is important in the pathogenesis of ATN and may become a future target for therapeutic intervention.
- Conservative management predominates for ATN. This entails careful fluid management and dialysis support as needed with prevention of complications.
- Review of the data regarding pharmacologic intervention for established ATN supports a trial of isotonic fluid repletion. Judicious use of intravenous loop diuretics may increase urine output, but their ability to have an impact on improved patient survival in AKI is still unproven. Similarly, the clinical data on “renal-dose” dopamine do not support its widespread use in established ATN.
- Recommendations for the azotemic patients who require radiocontrast procedures warrant a protocol of IV hydration and the use of nonionic iso-osmolar contrast material in the lowest dose possible. Treatment with *N*-acetylcysteine and/or special hydration with prestudy sodium bicarbonate may be considered as well.

kidney disease” should be defined as sustained kidney injury longer than 3 months resulting in a GFR of less than 60 mL/min/1.73 m² (National Kidney Foundation, 2002). These guidelines were updated in 2012 by KDIGO (KDIGO Committee, 2013; Levin and Stevens, 2014). A new classification system now includes the cause of kidney disease (if known), the estimated GFR (eGFR), and the level of albuminuria (Tables 46-4 and 46-5). The CKD category 3 has been further divided into category 3a (GFR 45 to 59 mL/min/1.73 m²) and 3b (30 to 44 mL/min/1.73 m²) based on data suggesting that outcomes differ between these two ranges of GFR. This new system (Fig. 46-5) better reflects the health implications for guiding prognosis and management (KDIGO Committee, 2013). For example, if a nephrectomy is performed and the remaining kidney is perfectly normal, the resulting eGFR may be 68 mL/min/m² but, in the absence of a cause for ongoing renal injury or albuminuria, the prognosis for

CKD progression is favorable (see Fig. 46-5). Alternatively, in a patient with diabetes, and an eGFR of 68 mL/min/1.73 m² and an albumin/creatinine ratio (ACR) >300 mg/g, there is a much higher chance of renal disease progression (see Fig. 46-5). This is because the level of albuminuria indicates that diabetes is a cause for ongoing chronic kidney injury. The 2002 classification system does not distinguish a difference. The 2012 guidelines based on the cause for reduced renal function (C), eGFR (G), and level of albuminuria (A), or CGA system, are much more useful for identifying risks and implementing referral/treatment strategies.

This distinction has now been incorporated into the reporting of the prevalence for CKD. In the 2013 USRDS report (U.S. Renal Data System, 2013), the prevalence of eGFR less than 60 mL/min/m² between 2005 and 2010 was 6.1%. Defined by ACR greater than 30 mg/g, the prevalence of CKD is 9.1%, which is similar to diabetes and higher than cardiovascular disease. When the combined prevalence of low eGFR and abnormal ACR are used, the prevalence of CKD is 13.1%. This is higher than the prevalence for diabetes or cardiovascular disease. This identifies CKD as an important health issue with a significant population burden.

After an initial kidney insult, if the acute injury does not completely resolve, a continuing attrition of functional nephrons occurs with time. Figure 46-6 depicts the renal failure continuum consisting of several stages of functional deterioration associated with specific clinical and biochemical abnormalities. Small changes

TABLE 46-4 Glomerular Filtration Rate Categories in Chronic Kidney Disease

GFR CATEGORY	GFR (mL/min/1.73 m ²)	TERMS
G1	≥90	Normal or high
G2	60-89	Mildly decreased*
G3a	45-59	Mildly to moderately decreased
G3b	30-44	Moderately to severely decreased
G4	15-29	Severely decreased
G5	<15	Kidney failure

*Relative to young adult level.

In the absence of evidence of kidney damage, neither GFR category G1 nor G2 fulfill the criteria for chronic kidney disease.

GFR, glomerular filtration rate.

From KDIGO Committee. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. Kidney Int Suppl 2013;3(1).

TABLE 46-5 Albuminuria Categories in Chronic Kidney Disease

CATEGORY	AER (mg/24 hr)	ACR (APPROXIMATE EQUIVALENT)		TERMS
		(mg/mmol)	(mg/g)	
A1	<30	<3	<30	Normal to mildly increased
A2	30-300	3-30	30-300	Moderately increased*
A3	>300	>30	>300	Severely increased†

*Relative to young adult level.

†Including nephrotic syndrome (albumin excretion usually >2200 mg/24 hr [ACR >2220 mg/g; >220 mg/mmol]).

AER, albumin excretion rate; ACR, albumin/creatinine ratio.

From KDIGO Committee. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. Kidney Int Suppl 2013;3(1).

CURRENT CHRONIC KIDNEY DISEASE (CKD) NOMENCLATURE USED BY KDIGO

CKD is **defined** as abnormalities of kidney structure or function, present for more than 3 months, with implications for health, and CKD is **classified** based on cause, GFR category, and albuminuria category (CGA).

Prognosis of CKD by GFR and albuminuria category

Prognosis of CKD by GFR and albuminuria categories: KDIGO 2012				Persistent albuminuria categories description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (mL/min/1.73 m ²) description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60-89			
	G3a	Mildly to moderately decreased	45-59			
	G3b	Moderately to severely decreased	30-44			
	G4	Severely decreased	15-29			
	G5	Kidney failure	<15			

Green: low risk (if no other markers of kidney disease, no CKD); Yellow: moderately increased risk; Orange: high risk; Red: very high risk.

Figure 46-5. Chronic kidney disease (CKD) risk for progression based on Kidney Disease: Improving Global Outcomes (KDIGO) 2013 classification of glomerular filtration rate (GFR) and albuminuria. in the serum creatinine levels correlate with significant alterations in the GFR when renal function is greater than 60 mL/min/1.73 m². This concept is illustrated by the serum creatinine ordinate on the left side of Figure 46-6, matched to the GFR line of identity crossing through the four different phases of progressive renal disease. However, the relationship between the serum creatinine level and the GFR changes as the renal function deteriorates below 60 mL/min/1.73 m². As noted on the right side of Figure 46-6, changes in the GFR (dashed, curved line) are represented by significantly larger increases in serum creatinine level depicted on the right ordinate. This is especially true in CKD as the GFR decreases to levels below 30 mL/min/1.73 m². Although an initial insult may decrease an individual's renal reserve, biochemical abnormalities are uncommon before the "renal-insufficiency" stage. After severe renal failure occurs, clinical symptoms become more common.

The degree of adaptation taking place at each stage determines the extent of clinical and biochemical abnormalities. When kidney function is minimally impaired (≤60% of normal), physiologic adaptation is complete. When the GFR falls below 20% of normal, progressive anorexia with nausea, salt retention, acidosis, insomnia, anemia, muscle fatigue, and worsening blood pressure (BP) control may occur. Structurally, after the GFR in humans falls below 50% of normal, a relentless progressive loss of function ensues even when the initial disease becomes inactive (Mitch et al, 1976). There is significant interest in those clinical and public health initiatives that can potentially identify and prevent progressive kidney failure. Clinical practice guidelines for CKD were developed and published by the NKF in 2002 to diagnose and treat CKD and its comorbidities more consistently (National Kidney Foundation,

2002; Patel et al, 2002; Eknoyan, 2003). These guidelines have been updated to incorporate more granularity to the original classification of CKD and to provide better prognostic information (KDIGO Committee, 2013; Levin and Stevens, 2014).

Although the clinical course of progressive renal disease as illustrated in Figure 46-6 moves through several different phases, which include decreased renal reserve, renal insufficiency, renal failure, and uremia, the K/DOQI (2002) guidelines, and now the KDIGO (2012) guidelines, have developed a more uniform classification of the stages of CKD with more relevant application for management (see Fig. 46-5). These guidelines will have an impact on education between patients and providers, will enhance the public's understanding of the different levels of kidney disease, and will promote the dissemination of specific research results for each stage.

Renal Mass Reduction and Chronic Kidney Disease

Deficits in nephron number predispose to progressive renal disease and hypertension (Chertow et al, 1996). Nephron number averages approximately 600,000 per kidney in the normal kidney with a standard deviation greater than 200,000 (Nyengaard and Bendtsen, 1992). Conceptually, a significant partial ablation of renal mass through renal insult or surgical partial nephrectomy initiates a cycle of progressive glomerular injury in the remnant kidney. In this setting, the injury is associated with hyperfiltration, glomerular hypertrophy, and systemic hypertension (Brenner and Mackenzie, 1997). In human studies, Novick and colleagues demonstrated that with a greater than 50% reduction in total renal mass, the extent of proteinuria correlated directly with the

Figure 46-6. The course of progressive renal disease. The course of a patient who began with normal renal function corresponding to a serum creatinine concentration of 0.6 mg/dL and a glomerular filtration rate (GFR) of 120 mL/min/1.73 m² is shown. **Y-axes.** The geometric serum creatinine ordinate at the left (B) applies to the solid line of identity (*open circles*), and the rectangles depict the various stages of progressive renal disease. The serum creatinine ordinate at the right side of the figure (C) should be used with the *dashed curve (ax-heads)* only. The ordinate at the extreme left (A), which describes the percentage of renal function remaining, applies generally. **Line of identity.** This line shows a decrease in function from 100% to 9% of normal corresponding to the diminution in GFR from 120 to 0 mL/min/1.73 m². The matching creatinine scale (A) is geometric. **Dashed curve.** Because GFR equals daily creatinine excretion/serum creatinine concentration and because the creatinine excretion is equal to daily production, which is constant, this equation is of the form $y = k/x$, which defines a hyperbola. This relationship remains valid during the course of chronic renal disease unless the creatinine production changes. The curve emphasizes that large changes in GFR may produce small and clinically imperceptible changes in serum creatinine concentration when overall renal function is near normal. Conversely, trivial changes in GFR produce large changes in serum creatinine concentration when the GFR is low. The rate of progression throughout the delineated stages depends on the nature of the underlying renal disease, host factors, treatment, and compliance with the medical regimen. (From Kimmel PL. Management of the patient with chronic renal disease. In: Greenberg A, editor. *Primer on kidney disease*. 2nd ed. San Diego [CA]: Academic; 1998. p. 434.)

duration of follow-up and inversely with the amount of renal tissue remaining (Novick et al, 1991). This observation suggests that ongoing renal injury occurs when a specific “set point” reduction in nephron number occurs. In certain population groups, birth weight may be a risk factor for progressive renal failure if associated with intrauterine growth retardation. Low birth weight can lead to a 20% decrease in overall nephron number (Lopes and Port, 1995; Hughson et al, 2003; Keller et al, 2003). Glomerular size in African-Americans is larger than in whites, possibly reflecting smaller nephron number (Pesce, 1998) and perhaps attributable to lower birth weight (Garrett et al, 1994). Theoretically, the increased risk for African-Americans to develop “nephrosclerosis” could be linked to this low-birth-weight risk concept. Allograft nephron number (donor kidney size compared with recipient body size) may be relevant in the development of chronic rejection and failure in human transplantation setting (Brenner and Mackenzie, 1997; Poggio et al, 2006). When the body mass of the donor is small, the functional demands on the allograft will be strained and may contribute with time to ongoing injury leading to allograft failure.

Interestingly, the age at loss of renal mass influences the kidney’s response in humans. In patients undergoing unilateral

nephrectomy for Wilms tumors, renal growth was most marked in those individuals who had surgery at a younger age (Di Tullio et al, 1996). This finding can be applied to the contrasting observations comparing outcomes in congenital solitary kidney versus surgical unilateral nephrectomy. The volume of glomeruli in a congenital solitary kidney is five to six times that observed in a normal kidney (Bhathena et al, 1985). This increase in volume is associated with a decreased nephron number and could explain the higher risk for ongoing parenchymal injury compared with surgical nephrectomy cases. In contrast, postdonation GFR seems to stabilize after an initial decrease from predonation values following nephrectomy in former kidney donors (Goldfarb et al, 2001; Ibrahim et al, 2009). These reports support the concept that the true response to decreased renal mass in humans varies according to age at time of reduction, underlying conditions (causative agent, etiology), and the actual degree of reduction.

Mechanisms of Progression

Apoptosis (programmed cell death) triggered by ischemia, toxins, or endogenous mediators of damage can be the initial insult that

causes renal damage. Apoptotic cell death is an active process under molecular control of regulatory proteins and is characterized by both morphologic and functional changes. These changes usually occur as a response to the cell and microenvironment in which the presence of certain “lethal factors” (e.g., tumor necrosis factor, Fas-ligand) or the absence of “survivor factors” (e.g., EGF, IGF-1, IGF-2, basic fibroblast growth factor [bFGF]) promote apoptosis. Lethal factors can either activate specific cell death receptors or damage the cells in the absence of receptor activation (Ortiz, 2000). Although growth factors regulate hypertrophy and cell proliferation, they may also mediate apoptosis as a healing response.

Cell death follows a reduction in nephron mass. The array of events that occur with progressive nephron mass loss include SNS activation, renal structural remodeling, and altered gene expression/regulation. Renal protective interventions are designed to counter those events that adversely affect the cortex and interstitium of the kidney. Both hemodynamic and nonhemodynamic factors are involved in the sustained renal injury after an initial insult. The hemodynamic events causing an increase in single nephron glomerular filtration rate (SNGFR) include increased glomerular plasma flow rates and capillary hydrostatic pressures in the remaining glomeruli. Elevated glomerular hydrostatic pressure is a major factor in renal injury after renal mass reduction (Meyer and Rennke, 1988). However, hyperfiltration alone in response to decreased nephron mass is not sufficient to induce pathologic glomerulosclerosis and interstitial fibrosis. Neurogenic factors and hypertension also play a significant role in ongoing renal injury. Increases in angiotensin II and NO activate the SNS, which plays a dominant role in the pathogenesis of hypertension in CKD (Myers et al, 1975). The rise in central SNS activity is generated by increased local expression of nitric oxide synthase (NOS)-mRNA and NO production coupled to an upregulation of NO production by interleukin-1 (IL-1) in the brain (Campese, 2000).

Nonhemodynamic mechanisms for renal injury involve a number of complex interactions for remodeling, including structural changes, growth factors, and cytokines. Abnormal glomerular growth is associated with, and may be a marker for, the activation of these specific mechanisms leading to sclerosis during the remodeling phase after renal injury (Fogo, 2000). Injury remodeling involving both glomerular hyperplasia (increase in cell number) and glomerular hypertrophy (increase in cell size) can occur within 2 days of a significant decrease in overall renal mass (5% nephrectomy). Glomerular growth can occur because of increases in any of the cellular components. Structural changes in the glomeruli during remodeling include increased extracellular matrix (ECM) production; glomerular hypertrophy; glomerular proliferation (increase in cell number: epithelial, endothelial, mesangial cells); and glomerular basement (GBM) modification (Ma and Fogo, 2009).

Foam cells are frequently located in segments of the glomerulus that are undergoing sclerosis and in the interstitium of diseased kidneys. Oxidized low-density lipoprotein (LDL) stimulates inflammation and fibrogenic cytokine production and can cause an increase in cell apoptosis and the production of ET and thromboxane. It also causes an increase in the release of renin from juxtaglomerular cells, thus enhancing vasoconstriction (Keane, 2000).

Many diseases have been associated with an imbalance of ECM synthesis and degradation (Ma and Fogo, 2009). The glomerular mesangial cell responds to various growth factors by proliferation and increased ECM production. An increase in collagen deposition and a decrease in the degradation of ECM components lead to interstitial fibrosis. The degree of tubular interstitial fibrosis has been closely correlated with the reduction in GFR in many different animal and human studies. Angiotensin II upregulates transforming growth factor- β 1 (TGF- β 1), which is a potent fibrogenic factor playing a key role in the pathogenesis of interstitial fibrosis. The major physiologic regulators of ECM degradation in the glomerulus are matrix metalloproteinases (MMPs) (Lenz et al, 2000). MMPs are distinct, matrix-degrading enzymes such as stromelysins, gelatinases, elastases, and interstitial collagenases. Changes in MMP expression or activity can alter ECM turnover, which in turn may

lead to glomerular scarring and a decline in renal function (Zhao et al, 2013). MMPs may also indirectly affect regulation of certain growth factors that play a role in ECM turnover. Conceptually, progressive glomerular sclerosis may result from this shift in ECM turnover toward increased matrix accumulation, a decreased filtration area, and progressive renal failure.

A wide range of conditions or substances can promote intrarenal growth and glomerular sclerosis in experimental models. These include a loss of renal mass, high-protein or high-salt diet, growth hormone, IGF-1, androgens, glucocorticoids, angiotensin, aldosterone, and ET. Aldosterone may promote fibrosis by means of several mechanisms including plasminogen activator inhibitor-1 expression with consequent alterations of vascular fibrinolysis through stimulation of TGF- β 1 and reactive oxygen species. Although significant evidence has accumulated to implicate angiotensin II in mediating renal disease, aldosterone is also an important factor in causing progressive renal disease through both hemodynamic and direct cellular actions. Circulating aldosterone may mediate vascular fibrosis by a direct interaction with high-affinity, low-capacity corticoid receptors located in the cytosol of vascular fibroblasts (Lea et al, 2009).

Angiotensin II upregulates the expression of multiple growth factors and cytokines. Angiotensin II actions, which are separate from the blood pressure effect, may contribute to progressive renal disease and this helps to explain the rationale for using ACE inhibitors and ARBs in patients with CKD. A number of cell-specific growth responses (glomerular cells, endothelial cells, glomerular visceral epithelial cells, mesangial cells) regulate glomerular growth. Endothelial cells inhibit smooth muscle cell migration and proliferation and produce vascular endothelial growth factors, NO, ET, and platelet-derived growth factor (Fogo, 1999; Ma and Fogo, 2009). Vascular endothelial growth factors stimulate angiogenesis, whereas ET promotes hypertrophy and increased mesangial cell matrix.

Genetic Factors

Family members of patients with kidney disease are disproportionately affected with progressive renal failure. The familial clustering of nephropathy has been reported in diabetes, hypertension, SLE, and HIV-associated nephropathy. Interestingly, an individual's family history of end-stage renal disease (ESRD) is a better predictor of the future risk for renal failure than is blood pressure or blood glucose (Freedman et al, 1997; Satko and Freedman, 2004; Gunzler et al, 2013). A study sponsored by the National Kidney Foundation of Singapore, which screened more than 210,000 adults with renal disease, demonstrated a significant relationship between a family history and proteinuria with the potential for future renal failure (Ramirez et al, 2002). An observation of ESRD in those who have donated previously and who are still living underscores the potential role of genetics in the development of renal disease. Although the absolute rate of ESRD following living donation is extremely low, one study identified that all 9 donors developing renal failure in long-term follow-up were family members (Mjoen et al, 2014), suggesting a genetic contribution.

Our understanding of those mechanisms involved in progression to sclerosis has expanded since the early 1990s. It is now clear that genetic traits may contribute to the structural and functional adaptations to a reduction in renal mass. In diabetes, genetic signaling in response to a metabolic injury may explain why only approximately 40% of those with type 1 diabetes mellitus develop diabetic nephropathy. In the Appropriate Blood Pressure Control and Diabetic (ABCD) study, the ACE DD genotype was the strongest predictor for the presence of nephropathy (14.2% of DD homozygotes exhibit nephropathy vs. 7.8% of non-DD homozygotes) (Jeffers et al, 1997). The Genetique de la Nephropathie Diabetique study demonstrated a significant association between the D-allele frequency and progressive nephropathy in type 2 diabetic patients (Marre et al, 1997). Even in nondiabetic glomerular injury (IgA nephropathy) there was a greater reduction in GFR and worse biopsies in patients carrying the D-allele. Not only does the

DD genotype impart increased risk of progression, but this genotype is also associated with an earlier need for dialysis. More recently, APOL1 has been identified as a genetic cause of kidney disease, especially on those of African-American background (Parsa et al, 2013).

It is hoped that large, collaborative genetic analyses will identify the genes underlying diabetic nephropathy and determine if the loci identified in previous smaller studies can be duplicated (Satko and Freedman, 2004; Satko and Freedman, 2005). The NKF sponsored the Kidney Early Evaluation Program (KEEP) and the Southeastern Kidney Council/ESRD Network. These programs are screening high-risk American populations to assess the link between family history and kidney disease (Brown et al, 2003).

Etiologies for Chronic Kidney Disease

The causes of progressive CKD parallel the most common causes of ESRD. Table 46-6 lists the incident causes of ESRD of varied causes by diagnosis from the U.S. Renal Data System (U.S. Renal Data System, 2013). Diabetes mellitus and hypertension account for the largest percentage of cases (63%) followed by glomerular diseases (14%). Urologic diseases account for only 2% of overall ESRD.

In patients younger than 40 years, CKD is most commonly caused by focal segmental glomerulosclerosis (FSGS), SLE, and then congenital abnormalities of the urinary tract or MGN. Membranoproliferative glomerulonephritis (MPGN), scleroderma, and autosomal dominant polycystic kidney disease (ADPKD) account for the many cases of CKD developing in patients between the ages of 40 and 55 years. In the cohort of patients older than 55 years, atheroembolic disease, paraproteinemia (multiple myeloma, amyloid), nephrosclerosis, and analgesic nephropathy are causes of CKD. The number of individuals older than age 70 who are developing CKD is growing exponentially. Note that in patients older than 40 years there is a significant burden of CKD as a consequence of diabetes and hypertension.

The primary parenchymal renal diseases that present the greatest propensity for progress are FSGS, RPGN, and MPGN. The development of CKD in patients with minimal change disease is rare in children and is also rare in adults undergoing a steroid-responsive clinical course. Patients at highest risk are those who do not respond to steroid therapy or who become late steroid nonresponders. The course of untreated FSGS is usually progressive to ESRD. Both children and adults usually develop ESRD 5 to 20 years from presentation. Malignant FSGS on biopsy exhibits a more rapid course to ESRD in 2 to 3 years. Those features associated with a more accelerated course are proteinuria greater than 10 to 15 g/day, SCr greater than 1.5 mg/dL at presentation, significant interstitial fibrosis, and glomerular sclerosis on biopsy.

TABLE 46-6 Incidence of Reported End-Stage Renal Disease by Detailed Primary Renal Diagnosis

DIAGNOSIS	PERCENT
Diabetes mellitus	38
Hypertension	25

Cystic kidney disease	5
Urologic	2
Unknown/Missing/Other	15

The data reported here have been supplied by the U.S. Renal Data System. The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government.

From U.S. Renal Data System. USRDS 2013 Annual Data Report: Atlas of Chronic Kidney Disease and End-Stage Renal Disease in the United States. Bethesda (MD): National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2013.

Although MPGN type 1 is a slowly progressive disease, type 2 is more aggressive with a higher percentage of sclerotic glomeruli, crescent number, and greater degree of interstitial fibrosis. These features portend a poor outcome. Progressive renal insufficiency can occur in 20% to 25% of patients with MPGN progressing to ESRD during the course of 20 years. At presentation, it is difficult to predict the renal outcome in most patients with membranous GN compared to those with MPGN.

Forty percent of individuals with IgA nephropathy progress to ESRD after approximately 20 years of clinical disease. Markers of poor outcomes are persistent hypertension, proteinuria greater than 2 g/24 hr, initial abnormal SCr at time of biopsy, and severe sclerotic changes and interstitial fibrosis on biopsy.

A number of systemic diseases involve the kidney and can lead to progressive renal insufficiency (Box 46-8). Progressive deterioration in renal function can occur in systemic vasculitis because of Goodpasture syndrome, granulomatosis with polyangiitis (formerly Wegener granulomatosis), Henoch-Schönlein purpura, and cryoglobulinemia with or without hepatitis C. Serologic tests (cryoglobulins, ANCA analysis, immune complex

markers, antibodies to hepatitis B or C, antistreptolysin O, hemolytic complement levels CH50 and C3), and biopsy of temporal artery or kidney are useful in classifying the clinical presentation into the correct vasculitis category. A significant glomerular insult on biopsy coupled with a poor response to therapy signifies patients at risk for developing worsening renal dysfunction and eventual ESRD.

In type 1 diabetic patients, 40% to 50% of patients will reach ESRD between 7 and 10 years after the onset of proteinuria. In most patients with type 2 diabetes mellitus, the time of onset is unknown, thus complicating the ability to predict the course of renal failure. Moreover, a significant percentage of patients have concomitant risk factors (smoking, hypertension, hyperlipidemia) along with the proteinuria and nephrosclerosis, and these factors may accelerate time to ESRD.

Monoclonal immunoglobulins or light chains in both the serum and urine are observed in dysproteinemic states of light-chain nephropathy, amyloid, and cryoglobulinemia. Patients usually present with undiagnosed increases in SCr and proteinuria and are usually older than 40 years. Treatment of light-chain deposition disease is suboptimal, with a significant percentage of patients progressing to ESRD if their presenting SCr values are greater than 4 mg/dL.

Malignancies of the gastrointestinal tract, breast, renal cell, prostate, or skin can mediate an immune complex nephropathy potentially leading to CKD. Urologic, gynecologic, and lymphoproliferative malignancies can also result in renal injury and progressive chronic renal insufficiency. Non-Hodgkin lymphoma is associated with MGN, and retroperitoneal tumors can cause ureteral obstruction and parenchymal infiltration, or both.

Certain hereditary diseases (sickle cell nephropathy, ADPKD, medullary cystic, aplastic, dysplastic, or hypoplastic kidneys) can also lead to CKD. ADPKD is the most common hereditary renal disorder leading to ESRD. Gene linkage may be helpful in identifying the ADPKD gene loci on the short arm of chromosome 16. This test can be performed in utero in children and in adults before cyst development. Only about 50% of ADPKD patients progress to renal failure. Risk factors for progression include male gender, African origin, early age of presentation, ADPKD 1 gene, hypertension, and gross hematuria (Grantham, 1997). Diverticular disease, cardiac valvular disease, and intracranial aneurysms are more common in ADPKD patients than in the general population and need to be considered in their care. Patients with ADPKD should be differentiated from those with acquired renal cystic disease (ARCD). ARCD develops in the setting of CKD and end-stage kidney disease and is a consequence of renal disease rather than a cause. The important correlation associated with ARCD is the increased incidence of renal cell cancer (Denton et al, 2002). Historically there has been no established correlation of ADPKD with renal cancer, although it may occur in this setting. This concept has been questioned in several pathologic studies identifying a higher incidence of tumors in ADPKD (Hajj et al, 2009; Jilg et al, 2013). It is unclear whether ADPKD itself contributes to cancer development or whether it is related to CKD/ESRD, similar to ARCD.

Medullary cystic disease sometimes can be confused with the benign condition of medullary sponge kidney. Medullary cystic disease presents in childhood with tubular cystic lesions at the cortical medullary junction and can be most accurately detected by kidney biopsy. The kidneys are usually small, and the disease progresses to ESRD at a variable rate.

Tubular interstitial disease is an uncommon cause of CKD. Clinical manifestations depend on the degree of involvement, the tubular sites involved, and the level of compensation that the uninvolved areas provide. The diagnosis of chronic interstitial nephritis depends on the urinalysis and clinical history. The urine findings are variable, and white blood cells may be present. Obtaining an accurate medication history is essential, considering the broad range of etiologies. Three percent to 20% of patients treated with lithium with the passage of time develop CKD (Boton et al, 1987). Chronic lead nephropathy may demonstrate a protracted course

that is gradually irreversible as evidenced by small contracted kidneys. Lead nephropathy can be associated with renal adenocarcinoma. Another form of chronic interstitial nephritis that progresses to ESRD is analgesic nephropathy. The course in analgesic nephropathy is variable depending on the number of pills consumed (Kuo et al, 2010).

Obstructive uropathy involving the ureter, bladder, or urethra can lead to progressive renal insufficiency. Undetected ureteropelvic junction obstruction and posterior urethral valves are the most common types of congenital causes for progressive renal failure. Newer spiral CT methods may prove helpful in identifying the obstructing lesion. Regaining renal function post-obstruction is dependent on both the degree and duration of obstruction (<2 weeks) and preservation of specific tubular acidifying abilities.

The percentage of the ESRD population whose condition is attributable to reflux nephropathy and nonreflux nephropathy has changed with time (Craig et al, 2000). In a study of pediatric renal failure trends in Australia and New Zealand, reflux represented a much larger proportion of the population in the 1970s than it did between 2002 and 2006 (Orr et al, 2009). Correspondingly, the incidence of hypoplasia/dysplasia increased during the same time period. There are debates regarding whether this may be attributed to changing disease categorization or more aggressive therapy of reflux. Finally, when stratified by age, reflux is more common in older children than hypoplasia/dysplasia, making it important for adult urologists to recognize. Women with reflux nephropathy demonstrate an increased risk of accelerated progression during pregnancy if the SCr is greater than or equal to 2.49 mg/dL. Vesicoureteral reflux may result in CKD from renal scarring. Vesicoureteral reflux may be either unilateral or bilateral, and progression to renal failure is related to the severity of reflux. Congenital reflux, particularly the higher grades, may be associated with renal dysmorphism where scarring is a nonpreventable consequence of maldevelopment. By contrast, acquired scarring is a consequence of pyelonephritis. It is this latter acquired group where aggressive management of reflux may prevent renal loss. Renal biopsy can be diagnostic, as well as prognostic, in obstructive nephropathy when relief of obstruction is not followed by restoration of renal function to baseline. A review of North American Pediatric Renal Trials Collaborative (NAPRTC) data showed that patients with reflux and CKD progressed to ESRD at a lower rate than those with aplasia, hypoplasia, or dysplasia (Novak et al, 2009). Furthermore a history of urinary tract infection on entry to the registry was a risk factor for progression to ESRD.

Through time, untreated urolithiasis can result in CKD (Saucier et al, 2010). Gupta and colleagues reviewed the natural history of 33 urinary stone patients with a presenting SCr greater than 2.0 mg/dL before surgical intervention and after placement of ureteral stent or percutaneous nephrostomy tube (Gupta et al, 1994). The mean decrease in SCr with treatment was 1.2 mg/dL. There was no statistical difference in the rate of decrease between patients with pretreatment SCr levels of 2 to 2.9 mg/dL versus those with greater than 3 mg/dL. Furthermore, in an epidemiologic study by Rule and colleagues (2009), residents from Olmsted County with a history of a documented kidney stone (n = 4774) were more likely to develop CKD after the initial diagnosis than controls (Rule et al, 2009).

RAS can result in progressive azotemia (Piecha et al, 2012; Textor et al, 2013). "Flash" pulmonary edema with oliguria and azotemia may suggest the presence of bilateral RAS, warranting further evaluation. Usually, when the SCr is greater than 3 mg/dL, there is an underlying parenchymal abnormality contributing to kidney failure, in addition to the RAS. Several large multicenter trials have demonstrated that intervention for RAS may not necessarily lead to renal functional improvement (RENAL Replacement Therapy Study Investigators et al, 2009; Cooper et al, 2014).

Accurately monitoring the rate of decline in residual renal function (RRF) is important to determine whether the observed change in RRF is consistent with the natural history of the underlying disease or the result of an acute insult. If the RRF decline is inconsistent, an evaluation to uncover an alternate cause is

warranted. Patients with CKD are at risk for acute renal failure from a broad range of causes. Nephrotoxic agents, infection, volume depletion, hypotension, progressive RAS, hypercalcemia, and hyperuricemia may all lead to worsening of underlying stable CKD as delineated in [Box 46-9](#).

BOX 46-9 Factors Associated with Acute Deteriorations in Chronic Kidney Disease

NEPHROTOXIC

Contrast-induced
Pharmacologic agents
Aminoglycoside antibiotics
Nonsteroidal anti-inflammatory drugs
Cyclooxygenase-2 inhibitors
Chemotherapeutic agents
Antirejection agents (cyclosporine, tacrolimus)
Anesthetic agents

AUTOREGULATORY DYSFUNCTION

ACE inhibitors
Angiotensin receptor blocker

ANATOMIC/STRUCTURAL

ADPKD and ACE inhibitors
Obstruction
Progressive renal artery stenosis
Renal vein thrombosis
Nephrolithiasis

HEMODYNAMIC/PERFUSION DISORDERS

Congestive heart failure
Perioperative hypotension
Volume depletion
Gastrointestinal: bleeding, diarrhea, vomiting
Excessive diuresis
Sepsis with vasodilation

PARENCHYMAL INJURY

Acute myocardial infarction
Valvular dysfunction
Superimposed “new” glomerulonephritis

INTERSTITIAL

Hypercalcemia
Hyperuricosuria
Atheroemboli

DRUG-INDUCED

Penicillin analogues
Cephalosporins
Sulfonamides
Rifampin
Diuretics
Thiazides
Furosemide

MISCELLANEOUS

Phenytoin
Allopurinol
Cimetidine

Clinical Assessment of Chronic Kidney Disease (Function, Proteinuria, Radiology, and Biopsy)

In practice, after the GFR decreases to less than 60 mL/min/1.73 m² for 3 months or more, patients are classified as having CKD ([Levin and Stevens, 2014](#)). The adjusted relative risk from a population survey adjusted for age, proteinuria, hematuria, and hypertension showed that changes in GFR occurred at a cutoff SCr value of 1.2 mg/dL (105 μm/L for women) and 1.4 mg/dL (125 μm/L for men) ([Couchoud et al, 1999](#)). However, in extrapolating SCr values to the actual GFR, the relationship was not linear (see [Fig. 46-6](#)). Furthermore, factors such as gender, race, and age affect serum creatinine levels independent of GFR.

Other measurements that complement the SCr value may provide a better index to the underlying predicted GFR. CrCl, CrCl plus urea clearance divided by 2, GFR measurements (inulin or iohalamate), and cystatin C all provide information on the level of renal function. Although the iohalamate GFR is the “gold standard” for measuring renal function, this test is not widely available. The Modification of Diet in Renal Disease (MDRD) (<http://www.mdcalc.com/mdrd-gfr-equation/>) and CKD-EPI (<http://www.qxmd.com/calculate-online/nephrology/ckd-epi-egfr>) equations are widely used throughout the world to estimate CrCl ([Levey et al, 2014](#)). Cystatin C, a 13-kilodalton nonglycosylated basic protein produced by all tissues, might include an advantage in detecting minor alterations in GFR ([Levey et al, 2014](#)). Cystatin C–based estimates for GFR do not require specification of race and may work better for patients with low muscle mass.

Most forms of CKD gradually and inevitably progress to ESRD throughout a 2- to 10-year time course, depending on the underlying renal lesion responsible for the CKD, combined with patient-specific factors. The KDIGO staging and approach to treatment of CKD currently depends on the cause of CKD, the assessment of GFR (function assessment), the level of proteinuria, and the clinical comorbidities. The National Institutes of Health Consensus Conference of 1993 recommended that patients with CKD be referred to a nephrologist when the SCr has increased to 1.5 mg/dL in females and 2 mg/dL in males ([Consensus Development Conference Panel, 1994](#)).

Renal Function Assessment

Although the SCr level is widely used as an index of renal function, SCr is affected by factors other than the GFR. At any given GFR, the SCr concentration is significantly higher in men than in women, and in blacks than in whites. Total CrCl usually exceeds the GFR because of tubular secretion, whereas the urea clearance is usually lower than the GFR because of tubular reabsorption. Some advocate that the mean of the creatinine and the urea clearance might provide an improved estimate of the GFR than either of these provide separately. Factors associated with creatinine excretion (age, gender, ethnicity, tubular creatinine secretion, and inhibition) might affect the accuracy of standard SCr measurements. Two notable drugs commonly used in clinical practice that interfere with tubular excretion of creatinine are trimethoprim and cimetidine. These can alter serum creatinine–based eGFR by inhibiting tubular creatinine excretion. The MDRD study equation to predict the GFR incorporates SCr concentration and demographic characteristics (age, gender, and ethnicity). It is more accurate than other more widely used predictive equations or parameters; however, it tends to underestimate GFR at higher GFR ranges. Although the MDRD study equation has gained popularity, a newer equation to estimate GFR has been published. This new model, the Chronic Kidney Disease Epidemiology (CKD-EPI) study equation, is expected to replace the MDRD study equation because it was developed using a combination of several studies in which kidney function was measured, including the MDRD Study ([Levey et al, 2014](#)). Although this equation retains the very good performance observed with the MDRD equation in subjects with eGFR below 60 mL/min/1.73 m², it further provides a lower bias in subjects

with better preserved GFR levels (Levey et al, 2009). More recently, an equation that incorporates not only serum creatinine but also cystatin C has been proposed. Using this equation, the estimation of GFR was found to be more precise and accurate, but also, importantly, the addition of cystatin C appeared to strengthen the association between low eGFR with the risk of ESRD and mortality (<http://mdrd.com>).

Although these equations are better than other standard measures for GFR, they are still inaccurate for patients not in a steady state for creatinine balance or those with a medical condition interfering with creatinine excretion or creatinine assay, or both (diabetic ketoacidosis or therapy with certain cephalosporins). These equations are still of doubtful application in subjects with no kidney disease and normal kidney function such as potential living donors. In donors, the remaining kidney is normal and there is no underlying cause of chronic renal injury. The KDIGO cause, GFR, albuminuria represents an improved method for classifying kidney disease and more accurately portraying disease progression risk (KDIGO Committee, 2013; Levin and Stevens, 2014).

Considering the K/DOQI and the new KDIGO staging of renal function linked to the level of GFR, a number of medical centers and commercial laboratories are using eGFR from SCr as a primary method for reporting kidney function because of inadequacies in SCr alone. The MDRD study equation is used most commonly to estimate GFR; however, it is expected that most laboratories eventually incorporate the CKD-EPI equation as the main method for estimating GFR. The estimation of GFR by any equation is not appropriate for patients who experience rapidly changing kidney function, are at the extremes of age and body size, exhibit malnutrition or obesity, are paraplegic or quadriplegic, consume a vegetarian diet, or have diseases that impact skeletal muscle status. Moreover, in sick, hospitalized patients with moderate to advanced renal failure, the MDRD equations and eGFR perform poorly when estimating GFR and are not reliable measurements of RRF (Poggio et al, 2005).

Proteinuria

Proteinuria is a marker for glomerular injury. Increased excretion of albumin is a sensitive marker for CKD attributable to diabetes mellitus, glomerular disease, interstitial disease, and hypertension. The American Diabetes Association and the NKF have historically recommended screening assessment using proteinuria measurement to detect CKD (Levey et al, 1998; American Diabetes Association, 2001). More recently, the revised KDIGO classification of CKD proposed to add the presence or absence of albuminuria to the stages of CKD, especially CKD stage 3. Studies suggest that this marker is as important as GFR in predicting mortality and ESRD (Astor et al, 2011). In adults, albuminuria can be identified by the use of albumin dipstick, urinary albumin concentration, ACR measured in a spot morning urine sample, or 24-hour urinary albumin excretion (Gansevoort et al, 2005). The standard urine protein dipstick is insensitive for low concentrations of albumin (<10 mg/dL) and for some immunoglobulin light-chains. Dehydration, hematuria, exercise, infection, and extremely alkaline urine (pH >8) can cause false-positive dipstick readings. Alternatively, a random urine protein/creatinine ratio can also be used for the assessment and management of patients with established CKD (see Table 46-5). This approach provides an assessment of proteinuria comparable to a 24-hour urine collection. Exceptions are in subjects with large variations in muscle mass (either low or high) in which the ratio could be distorted.

Radiographic Assessment

The radiographic assessment of CKD patients should take into account the impact of iodinated contrast on the RRF. Imaging techniques in CKD are usually used for the investigation of new AKI or for the investigation of potential problems in nonrenal sites (e.g., cardiac catheterization, peripheral vascular concerns, abdominal

investigations). Contrast material can induce the worsening of underlying renal disease to the point of requiring RRT. The diagnostic importance of the contrast study must be weighed against the risk of contrast-induced injury so that the significance of the potential findings justify any downside risks. All patients with an eGFR less than 30 mL/min/1.73 m² should be considered for alternative diagnostic testing. For an eGFR between 30 and 60 mL/min/1.73 m², prophylactic preventive strategies to avoid worsening renal function should be implemented. Specific measures may help lower the risk for AKI in patients with CKD who are undergoing radiographic assessment. These include volume expansion, hydration with IV administration of normal saline solution (sodium chloride 0.9%), using low-osmolar contrast or iso-osmolar contrast media, and using minimal doses of contrast. Alternatively, noncontrast imaging techniques such as CO₂ angiography should be used. Avoiding short intervals between contrast studies might also be of help (Thomsen, 2003; Liss et al, 2005). See Prevention of Acute Tubular Necrosis for recommendations. The use of gadolinium instead of iodinated contrast material should be considered for those subjects with more preserved kidney function (>30 mL/min/1.73 m²), always keeping in mind the risk for nephrogenic systemic fibrosis (NSF) (Manjunath and Perazella, 2011; Perazella and Reilly, 2011).

The value of normal saline solution hydration in patients with CKD and diabetes mellitus to decrease the risk for contrast-induced nephropathy is established (Solomon et al, 1994). Although no additional benefit to mannitol has been shown in the diabetic patient undergoing radiocontrast procedures, sodium bicarbonate solution infusion along with *N*-acetylcysteine may potentially be of help. The antioxidant *N*-acetylcysteine (600 mg orally twice a day on the day before and on the day of administration of the contrast agent) along with hydration using a 0.45% saline solution intravenously may decrease the risk of AKI from radiographic contrast agents in this patient group, although debate exists regarding the value of this intervention (O'Sullivan et al, 2013).

Although not a cause of AKI or a trigger to progression of CKD, the use of gadolinium for imaging techniques such as magnetic resonance imaging (MRI) has become a matter of significant concern for subjects with moderate to advanced CKD. The association between the use of gadolinium-based agent contrast and NSF is established (Perazella, 2008; Reiter et al, 2012). NSF is a systemic condition characterized by fibrosis in several organ sites. NSF in patients with ESRD who have received gadolinium has been universally described with fibrosis of the skin. Symmetrical, bilateral fibrotic indurated plaques or subcutaneous nodules characterize this condition. The feet, ankles, shins, and hands are common initial sites of involvement followed by extension to more proximal areas of the extremities, trunk, and buttocks. Skin involvement occurs in all cases, with systemic organ involvement being more variable. Connective tissues and muscles can be involved, which limits range of motion in these patients. Other visceral organs can also be involved. The diagnosis is clinical and histopathologic. The natural history of NSF is characterized as progressive, leading to a high mortality rate, although the disease may stabilize in a small percentage of subjects.

Gadolinium is a nonionic, hyperosmolar contrast agent excreted unchanged by the kidney, so its half-life (about 1 to 1.5 hours in subjects with normal kidney function) is prolonged with decreasing kidney function. Several types of gadolinium formulations are available, and NSF has been described with all of them, although the risk may vary depending on the formulation. In contrast to iodinated contrast agents, gadolinium does not seem to have a direct nephrotoxic effect, but its toxicity to other tissues when not renally excreted is of concern.

Avoidance of gadolinium in patients with advanced kidney disease (<30 mL/min/1.73 m²) or on dialysis treatment is the main preventive strategy because no effective treatment exists after the disease has initiated (Perazella, 2008; Perazella and Reilly, 2011; Reiter et al, 2012). If the use of gadolinium is absolutely required (benefit of study outweighs risks), then HD treatment

should immediately follow the administration of gadolinium in those patients already on dialysis. PD seems not to be efficient in removing the agent, and thus a few HD sessions should be considered if gadolinium administration is unavoidable.

Urinalysis and Kidney Biopsy

The urine sediment examination is helpful in detecting CKD and in identifying the type of kidney disease. All patients with CKD should undergo a urinary sediment examination. Cells can originate from the kidney or from other sites within the urinary tract. The presence of a RBC cast strongly suggests glomerulonephritis, especially if the patient is dysmorphic. Urinary eosinophils are usually associated with allergic tubular interstitial nephritis although a study challenges that notion (Muriithi et al, 2013). If the urinalysis is negative, despite the patient's having apparent CKD, a second specimen should be examined at another time. The urine sediment should be examined because urinary dipsticks cannot detect tubular epithelial cells (that are casts in the urine), crystals, fungus, or parasites.

A renal biopsy is not usually performed to evaluate asymptomatic hematuria but is warranted if the GFR is less than 60 mL/min/1.73 m² and the urinalysis is abnormal. The approach to performing kidney biopsy, whether closed (CT-guided, ultrasonography-guided) or open (standard or laparoscopic), depends on the overall clinical status, body habitus, patient's clotting parameters, and cumulative experience of the physician. The structural severity of glomerular injury and the immunopathologic category of disease are helpful in predicting renal outcome.

Renal Protective Strategies

Regardless of the nature of the initial insult, after a critical number of nephrons are destroyed, a steady decline in GFR occurs as the progressive loss in viable nephrons occurs. Strategies for delaying the relentless loss in nephron mass (Brenner, 2003) are inconsistently used across a population with CKD. Yet, it is becoming increasingly clear that well-designed renal assessment and management programs are feasible and can be applied systematically to large numbers of CKD patients to decrease the rate of progression.

A report of the International Society of Nephrology 2004 Consensus Workshop on Prevention of Progression of Renal Disease (Zandi-Nejad and Brenner, 2005) identified a number of therapeutic measures to prevent the progression of CKD, including lifestyle modifications, blood pressure control, glycemic control, reduction of proteinuria, protein restriction, lipid control, avoidance of nephrotoxic agents, early referral to a nephrologist, correction of anemia, optimization of calcium-phosphorus product, correction of acidosis, and maintenance of fluid balance.

Various pharmacologic trials comparing different medications have shown that patients with better blood pressure control have significantly slower rates of deteriorating kidney function. New guidelines are available for treatment of hypertension in CKD (James et al, 2014). For patients with CKD, drug therapy should target blood pressure lower than 140/90 mm Hg. Drugs that block the renin-angiotensin system such as ACE inhibitors or ARBs are now first-line antihypertensive medications for patients with CKD. Conceptually, angiotensin II is critical in causing progressive renal disease by both hemodynamic and non-hemodynamic mechanisms. Blockade of the renin-angiotensin system contributes to the preservation of renal function by decreasing intraglomerular pressure and proteinuria. Because proteinuria plays a sentinel role in renal scarring, a reduction in proteinuria correlates with slowing of disease progression. A meta-analysis of randomized clinical trials confirmed the predictive value of proteinuria and the renal protective effect of proteinuria reduction by ACE inhibitor therapy in large patient series (Chiurchiu et al, 2005). Clinical research findings support the view that preservation of renal function through angiotensin blockade can be achieved in

patients with either diabetes mellitus or nondiabetic nephropathy (Kshirsagar et al, 2000b). Reductions in proteinuria are greater with ACE inhibitors than with any other antihypertensive agent at the same level of blood pressure control. Multiple ACE inhibitors have been evaluated in CKD. In the Microalbuminuria Cardiovascular and Renal Outcomes—Heart Outcome Prevention Evaluation (MICRO-HOPE) a subset of 35,077 patients with diabetes mellitus and microalbuminuria were treated with ramipril (Mann et al, 2001). Ramipril reduced the progression from microalbuminuria to overt nephropathy by 24% ($P = .027$). In the ACE Inhibitor in Progression of Renal Insufficiency (AIPRI) study, only part of the risk reduction in the ACE inhibitor group could be explained by the antihypertensive or antiproteinuric effect (Maschio et al, 1996). The AIPRI group performed a meta-analysis of 11 randomized clinical trials consisting of 17,060 patients with nondiabetic renal disease. This study included the conclusion that antihypertensive regimens containing ACE inhibitors are more effective in slowing progression than regimens without ACE inhibitors. This finding was also observed in the Ramipril Efficacy in Nephropathy (REIN) Study (GISEN Group, 1997). Jafar and colleagues (1999) proposed that ACE inhibitors act by mechanisms in addition to their blood pressure-lowering and antiproteinuric effects (Jafar et al, 1999).

ARBs inhibit the type I angiotensin II receptor. Two large prospective, randomized trials have demonstrated that ARBs delay the progression of CKD in type 2 diabetic patients with overt nephropathy (Lewis et al, 2001; Parving et al, 2001). The Irbesartan Diabetic Nephropathy Trial (IDNT) examined the effect of ARBs (irbesartan) versus conventional therapy or the CCB amlodipine in 1715 patients with type 2 diabetes. The doubling of serum creatinine was 29% ($P = .009$) and 39% ($P < .001$) less than the risk in placebo and amlodipine-treated groups, respectively. Moreover, the Microalbuminuria Reduction with Valsartan (MARVEL) trial (Parving et al, 2001) supported the view that ARBs can potentially retard the progression of CKD in patients with type 2 diabetes.

Combining ACE inhibitors and ARBs may lead to further reductions in CKD progression, along with blood pressure, proteinuria, and microalbuminuria; however, a study has questioned this approach because of safety (Fried et al, 2013). Patients in this study received an ARB and were then randomized for the additional receipt of an ACE or a placebo. The study confirmed modest benefit for progression of renal failure in the dual therapy group, but this attenuated with time. There was no mortality or cardiovascular benefit for dual therapy. The study was stopped because of safety concerns related to hyperkalemia and AKI in the dual-treated group (Fried et al, 2013). Some CKD patients on ACE inhibitors might experience an acute decrease in reserve renal function with low renal perfusion states because of dehydration, congestive heart failure, and hypotension. Individuals with bilateral RAS and ADPKD patients with cyst size larger than 10 cm may also experience a decrease in reserve renal function while on ACE inhibitor therapy. A rise in serum creatinine of more than 1 mg/dL after beginning ACE inhibitor therapy should prompt a clinical evaluation to explain the change in baseline function.

An intricate relationship exists between hemodynamic factors that regulate vascular tone and metabolic factors that govern circulating lipids. It is now apparent that the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors reduce production of molecules involved in fibrogenesis, reduce mesangial and smooth muscle cell proliferation, and decrease production of integrin adhesion molecules (Keane, 2000). Although HMG-CoA reductase drugs can be part of the CKD treatment regimen, they are associated with a reduction in proteinuria and did not lead to GFR improvements (Navaneethan et al, 2009b). Their main advantage remains cardiovascular protection (Navaneethan et al, 2009b).

For more than 25 years it has been known that protein restriction can ameliorate many symptoms of renal insufficiency and prevent its progression (Fouque and Laville, 2009). However, without regular dietary consultation, patients on a low-protein diet may experience a decrease in protein intake and deterioration of several nutritional parameters. A number of different diets have been used to help slow the progression of CKD. These dietary formulations

include low-protein (0.6 g protein/kg ideal body weight) diets, very-low-protein diet (0.3 g protein/kg/day predominately vegetable protein) supplemented with essential amino acids, or very-low-protein diet supplemented with both essential amino acids and nitrogen-free analogues of amino acids (ketoacids). The overall dietary requirement in CKD is approximately 0.6 to 0.8 g of protein/kg/day (Fouque et al, 2011). An in-depth analysis of the MDRD study results did note that each 0.2-g/kg/day reduction in protein intake was associated with a 29% slower rate of loss of GFR and a 51% prolongation in the time to dialysis for nondiabetic patients (Mitch, 2000). Several additional studies have demonstrated the beneficial effect of dietary protein restriction on retarding the progression of CKD in both diabetic and nondiabetic patients (Pedrini et al, 1996; Kasiske et al, 1998; Fouque and Laville, 2009).

Table 46-7 summarizes a comprehensive strategy to achieve renal protection in patients with CKD (Jafar et al, 1999; Zandi-Nejad and Brenner, 2005; James et al, 2014). The comprehensive

strategy illustrates specific interventions, treatment approaches, monitoring, and target benchmarks of treatment.

Preoperative Evaluation of Patients with Chronic Kidney Disease and End-Stage Renal Disease

In CKD/ESRD patients scheduled for an elective surgical procedure, a thorough preoperative assessment to define risk is warranted (Trainor et al, 2011). Preoperative risk falls into three categories: patient-specific, procedure-specific, and anesthesia-specific risks (Bronson, 2000). CKD patients should be closely evaluated because they may exhibit multiple comorbidities that would affect outcome. The risk of a specific procedure is proportional to the physiologic stress associated with the procedure. The American Society of Anesthesiologists physical status scale defines five classes, each with a specific 7-day mortality from 0.07% (no organic or psychiatric disease) to 33.58% (moribund with little chance of survival). However, this scale does not consider procedure-related risks. There is no set risk profile specific for CKD. In general, procedures associated with a higher level of risk include major joint replacement, craniotomy, cardiac procedures, large bowel procedure, and exploratory laparotomies. The anesthesia-specific risk takes into account the effects of anesthetic agents and physiologic responses to a host of possible operative events such as hypotension, hypertension, blood loss, tachycardia, hypoxia, myocardial depression, and the acute worsening of renal function. **In the CKD/ESRD population the major predictors of cardiac events are the presence of active ischemia, poor left ventricular function, and baseline ventricular arrhythmia.**

Formal cardiac testing may be warranted preoperatively for patients with established ischemia, ventricular arrhythmias, and abnormal left ventricular ejection fraction. Although it is preferable to obtain an exercise imaging study rather than pharmacologic imaging study, a significant percent of CKD/ESRD patients will not achieve maximal predicted heart rate secondary to limited exercise capacity and medications. Pharmacologic testing with dobutamine stress echocardiography may be the best screening test for coronary disease in CKD (Marwick et al, 1998). A negative study showed a low frequency of events during the short term (Chertow et al, 1997).

Hypertension also plays a role in determining operative risk. A blood pressure of 180/110 mm Hg or more is associated with a greater risk for preoperative ischemic events. When possible, surgery should be delayed to bring blood pressure down to an acceptable level in patients with hypertension and CKD (James et al, 2014).

CKD patients with chronic obstructive pulmonary disease, active asthma, or a current infection are at high risk for pulmonary complications. Upper abdominal and thoracic surgeries carry the greatest risk of compromising pulmonary function. If the forced expiratory volume vital capacity in 1 second (FEV₁) is greater than 2 L, the risk of a complication is low. An FEV₁ less than 1 L is associated with a significantly greater risk. Discontinuing smoking at least 3 months before surgery can significantly decrease the risk of pulmonary complications.

CKD patients with diabetes mellitus should achieve optimal control (<200 mg/dL) before surgery. The risk for infectious complications increases with blood sugars greater than 300 mg/dL. CKD patients with diabetes mellitus on oral hypoglycemic agents should be carefully monitored because hypoglycemia with sepsis and/or malnutrition can markedly increase morbidity and mortality.

Elective surgery should be avoided in CKD/ESRD patients in a malnourished state. Serum albumin less than 3.5 g/dL, prealbumin less than 30 mg/dL, protein-nitrogen appearance or protein catabolic rate less than 0.8 g/kg/day, and subjective global nutritional assessment score of less than 5 signify malnutrition. Nutritional (protein/calorie) supplements should be used preoperatively to improve the baseline nutritional status. In the setting of anorexia, all offending drugs should be eliminated and consideration given for using pharmacologic appetite-stimulating agents (megestrol acetate).

TABLE 46-7 Comprehensive Renoprotection Strategy for Chronic Kidney Disease

FOCUS AREA	GOAL	TREATMENT
Blood pressure control	<140/90 mm Hg	ACE inhibitor ARB Salt restriction Diuresis
Reduction in proteinuria	<0.5 g/day	ACE inhibitor ARB ? Aldosterone blockade
Glycemic control	Hb _{A1C} <7%	Oral hypoglycemic agents Diet Insulin
Dietary protein restriction	0.6-0.8 g/kg/day*	Dietary consult
Lipid lowering	LDL ≤70 mg/dL†	Statin‡ Triglyceride-lowering agent
Anemia management	Hb at 11-12 g/dL	Erythropoietin Iron
Lifestyle modifications	Ideal body weight* Smoking cessation Exercise 3x/wk Depression modification	Weight-loss program (dietary counseling, surgery) Antidepressants
Calcium × phosphorous product	Ca × phos. product <55 Phosphorus <5.5 mg/dL Intact PTH 70-110 pg/mL (CKD stage 4) 30-70 pg/mL (CKD stage 3) 25 (OH) vitamin D >30 ng/mL	Vitamin D supplementation Use dietary phosphorus restriction Phosphate binders

*Avoid malnutrition.

†Consider measuring nontraditional risk factors: homocysteine, lipoprotein A, C-reactive protein, fibrinogen.

‡Treat hyperhomocysteinemia with folic acid.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CKD, chronic kidney disease; Hb, hemoglobin; LDL, low-density lipoprotein; PTH, parathyroid hormone.

Drug dosing in CKD/ESRD should be closely monitored to avoid both reversible and irreversible toxicities. Avoiding drugs that have the potential to accelerate loss of renal reserve function is of paramount importance. The risk of adverse events may be linked to the patient's degree of residual renal dysfunction. Uremic toxins might modulate cytochrome P450 enzyme activity, decrease glomerular filtration of drugs, and alter tubular secretion. High-risk therapies in the setting of CKD-ESRD include ACE inhibitors, radiographic contrast, volume depletion, NSAIDs, cyclooxygenase-2 inhibitors, and aminoglycosides.

Conservative Management: Prevention of Uremic Complications

A comprehensive approach to achieving optimal renal care begins with the early detection of renal failure followed by the initiation of interventions that delay progression, prevent uremic complications, modify comorbidities, and when necessary prepare patients for RRT to optimize patient survival (Pereira, 2000).

Decreased GFR is associated with complications in most organ systems. The most important CKD-related complications include hypertension, anemia, malnutrition, bone disease, neuropathy, and alterations in quality of life. As the patient moves from a stage 2 to higher stages of CKD, they are more likely to develop additional comorbidities. The level of scrutiny and the search for comorbidities increases as the stage of kidney disease advances. A number of factors increase cardiovascular risk. These include diabetes mellitus, hypertension, dyslipidemia, smoking, physical activity, psychological factors, anemia, arterial stiffness, vascular/valvular calcifications, and calcium and metabolic bone disease status.

Attention to risk factors is critical to extend survival because a large percentage of patients with CKD die of cardiovascular events before reaching dialysis (Chronic Kidney Disease Prognosis et al, 2010). The Eighth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC8) has updated their guidelines (James et al, 2014). In patients with CKD who are older than 18 years, initial therapy should include an ACE inhibitor or an ARB for blood pressure control that targets blood pressure less than 140/90 (James et al, 2014). These agents provide for renal protection in addition to blood pressure control.

Traditional atherosclerotic risk factors are frequently present in CKD. Low HDL, elevated homocysteine, elevated LDL, and elevated lipoprotein A all define patients at high risk for cardiovascular events warranting lipid-lowering therapy and close cardiovascular screening. The Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) in 2001 suggested that based on results from the Heart Protection study and the PROVE-IT study, additional benefit may be achieved by reducing LDL cholesterol levels to substantially below 100 mg/L, especially in high-risk patients (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). Not only should patients use medications before stage 5 of CKD, but these medications should be maintained after the patient is transplanted. A meta-analysis comparing the efficacy of various antilipidemic therapies for PD, HD, and transplant recipients demonstrated the effectiveness of HMG-CoA reductase inhibitors (Massy and Kasiske, 1996). This has been confirmed with an updated report (Navaneethan et al, 2009b). Both statin and fibric acid derivatives have proven effective, although individual differences mandate periodic monitoring of fasting lipid levels and liver function tests. Updated information suggests statin treatment in established dialysis patients should be different. Two large multicenter randomized controlled trials in which two different statins were compared with placebo in HD patients showed no difference in preventing all-cause and cardiovascular mortality despite their efficacy in lowering LDL cholesterol (Wanner et al, 2005; Fellstrom et al, 2009). Based on these studies, the use of statins to prevent mortality in dialysis patients is not warranted (Navaneethan et al, 2009a).

Cigarette smoking is universally recognized as an independent risk factor for cardiovascular disease and should be discouraged with this disease. There is a significant association between current

smoking and cardiovascular outcomes, which further emphasizes the importance of smoking cessation.

Both vascular calcification and valvular calcifications have been found to be more common in CKD patients and these present an impact on survival (Blacher et al, 1999). Although there are no randomized trials that have evaluated whether treatment of calcium-phosphorus abnormalities or the use of calcium-based phosphate binders reduces the risk of CVD outcomes, the recommendation from K/DOQI clinical practice guidelines for bone metabolism and disease in CKD is that noncalcium-based binders be used if there is evidence of severe vascular calcification (Malberti, 2013). The stage of CKD in which bone disease begins to develop has not been well documented, nor has a consensus been reached regarding the optimal screening methods for identifying early abnormalities of calcium-phosphorus metabolism and bone disease in CKD patients. Below a GFR of approximately 60 mL/min/1.73 m², there is a higher prevalence of abnormalities of bone metabolism.

Overweight and obesity are associated with increasing risks for a variety of cardiovascular complications and with higher all-cause mortality. Weight reduction is an important lifestyle modification for overweight patients. Although protein-energy malnutrition and wasting are common among CKD patients, no single nutritional marker is helpful in defining malnutrition. Changes in lean body mass throughout time in CKD may signal not only worsening uremia but also an increased risk for CVD. Specific methods for evaluating a rise in nutritional status include multifrequency bioimpedance, dual x-ray absorptiometry, subjective global assessment, and hand-grip strength.

All diabetic patients with CKD should follow the American Diabetes Association's guidelines for blood glucose control. The target for diabetes control should be a hemoglobin A_{1c} level of less than 7%, a preprandial glucose level of 80 to 100 mg/dL, and a bedtime glucose level of 100 to 140 mg/dL.

Observational studies have shown an association between anemia and adverse cardiovascular outcomes in CKD patients. It is unclear whether treatment of anemia prevents cardiovascular events in CKD patients, but one study showed that targeting higher hemoglobin levels closer to normal ranges was associated with worse cardiovascular outcomes (Singh et al, 2006). Recombinant human erythropoietin (rHu-EPO) is most likely to benefit the CKD patient who is symptomatic with a hematocrit value less than 30%. As recommended by the KDIGO 2012 guidelines, the treatment goal should be to achieve hemoglobin between 10 and 11 g/dL (KDIGO Committee, 2013). Hypertension can be more difficult to control as the hemoglobin is increased with EPO therapy.

Cardiovascular disease begins early in the course of CKD. Among patients with CrCl of less than 25 to 30 mL/min, left ventricular hypertrophy is present in 38% to 45% of patients compared with a prevalence rate of 16% to 31% among patients with higher levels of RRF. Noninvasive testing of patients with kidney failure for cardiovascular disease is helpful, especially in high-risk patients. The diagnostic accuracy of perfusion imaging is lower than in patients not in renal failure. Dobutamine echocardiography has been reported to have a sensitivity of 96% and a specificity of 86% and is the preferred screening instrument for coronary artery disease in CKD/ESRD patients (Marwick et al, 1998). Aggressively addressing comorbidities in CKD that may shorten survival is critical to extending life years for these patients.

Initiation of Renal Replacement Therapy

The 2012 KDIGO guidelines recommend the initiation of dialytic therapy when one of the following are present: symptoms or signs of uremia, inability to control blood pressure or volume, progressive deterioration of nutritional status, or cognitive impairment (KDIGO Committee, 2013). Late complications of renal failure will likely manifest after the GFR is lower than 10 mL/min/1.73 m². It is ideal, however, that patients are evaluated for initiation of RRT and, importantly, for possible preemptive renal transplantation when GFR is below 20 mL/min/1.73 m². Despite

these recommendations, a significant percentage of patients have renal reserve capacity less than 10 mL/min/1.73 m² at the start of dialysis. Obrador and colleagues examined data on 90,897 patients who began dialysis in the United States from April 1995 to September 1997 (Obrador et al, 1999). The mean \pm standard deviation SCr level at initiation was 8.5 \pm 3.8 mg/dL. The mean predicted GFR was 7.1 \pm 3.1 mL/min/1.73 m². Historically, mortality among late referrals is consistently higher than among those with more timely initiated RRT patterns. Predictors of delayed referral among a retrospective cohort of 362 predialysis patients included age 65 years or older, female gender, and congestive heart failure (Holland and Lam, 2000). For HD, mortality is highest early after its initiation (Robinson et al, 2014).

The rationale for timely initiation of RRT is based on several different, independent lines of evidence. As renal function declines, spontaneous dietary protein restriction occurs. Declining renal function is associated with abnormal protein metabolism, malnutrition, and poor clinical outcomes. A lower serum albumin level correlates with an increased mortality risk for both HD and PD patients.

End-Stage Renal Disease Demographics and Treatment Options

There is a steady growth of ESRD patients (CKD stage 5) on RRT throughout the world. The incident rate for ESRD in the United States in 2011 was 357 new cases per million of population (U.S. Renal Data System, 2013). The incidence of ESRD has minimally declined from 2005 to 2011; however, the number of prevalent cases continues to increase (U.S. Renal Data System, 2013). The number of patients with ESRD in the United States is approximately 600,000. The number of transplants has remained relatively unchanged at between 16,000 to 17,000/year, with 9500 to 10,500 deceased donor transplants and 6000 to 7000 living donors each year. There has been a 13% decline in living donation since 2004 and a change in the demographics of the donors (Rodrigue et al, 2013).

Critically important to all ESRD patients is a thorough understanding of dialysis practices that yield improved outcomes. The Dialysis Outcomes and Practice Patterns Study (DOPPS) is a prospective, longitudinal study of HD practices from seven countries with large populations of dialysis patients (France, Germany, Italy, Japan, Spain, United Kingdom, and United States) (Young, 2000). Linking the DOPPS scope of work with the K/DOQI and now KDIGO goals will help to develop continuous quality improvement programs and provide direct feedback to participating dialysis centers worldwide (Augustine et al, 2004). The DOPPS has collected information that will affect issues that relate to anemia management, modifiable HD practices to optimize outcome, vascular access, mortality and hospitalization, nutritional indicators, depression assessment, prescription use, acidosis, and vitamin prescriptions (Pisoni et al, 2012).

The mortality rate of RRT patients is strongly influenced by the percentage of enrolled diabetic patients, the dialysis dose, the type of HD membrane, erythropoietin therapy, and the nutritional status. Adjusted mortality rates of prevalent dialysis patients in the United States are now falling (www.USRDS.org).

Poor long-term survival of ESRD patients is illustrated by comparing the expected remaining lifetime on dialysis or transplant with the general U.S. population (U.S. Renal Data System, 2013). The expected remaining lifetimes for dialysis patients were only one fourth to one sixth of those of the general population. By modality, the expected lifetimes for transplant patients were 2 to 3 times those of dialysis patients. Expected remaining lifetimes in transplant patients are now 70% to 80% of those of the general population. For the ESRD population, females have poorer outcomes as compared with males in terms of more frequent hospitalizations, frequency of anemia, vascular access problems, malnutrition, poorer quality of life, and access to transplantation (Sehgal, 2000).

Multiple RRTs are available for treatment of ESRD patients. The most commonly used RRTs are HD, PD, and renal transplantation. Other treatment options include hemodiafiltration (combination of intermittent hemofiltration with simultaneous HD) and nocturnal home HD (slow-flow HD for an extended period overnight). Outcome comparison suggests that renal transplantation is still the best overall treatment for ESRD patients, despite advances in dialytic options. The time on dialysis may have an impact on the success of replacement therapy. Patients on HD for more than 10 years have a poorer outcome when transplanted as compared with individuals receiving transplants with less time on dialysis (Meier-Kriesche et al, 2000). This finding is probably related to fixed vascular defects that occur in patients on chronic dialysis therapy. Reports confirm that longer waiting time on dialysis negatively affects post-transplant graft and patient survival (Meier-Kriesche et al, 2000). This effect was independent of age, race, donor characteristics, and original disease. Therefore patients who reach ESRD should undergo preemptive transplantation or transplantation as soon as possible after they are on dialysis.

In comparing outcomes between different RRTs for nondiabetic patients, it is essential to consider the type of statistical model used to evaluate mortality (Cox proportional hazards regression vs. Poisson regression), the type of analysis used (intent to treat vs. as treated), and the type of study patient (prevalent vs. incident) (Vonesh et al, 2000). Vonesh and colleagues reported that specific results are closely linked to stratification by age and modality (Vonesh et al, 2004). Appropriate patient selection is critical to optimizing the life years per patient with ESRD. PD provides an early survival advantage compared with HD, whereas patients older than 45 with diabetes may have a survival advantage (in months) if started on HD.

Not all patients will benefit from RRT. Recommendations for withholding or withdrawing dialysis from suboptimal adult ESRD patients have been published. These were based on feedback from the U.S. Renal Physicians Association (RPA) and American Society of Nephrology (ASN) in conjunction with broad representation from ESRD patients, family, and non-nephrologists (Galla, 2000; Fissell et al, 2005).

Currently in the United States 93% of dialysis patients are treated with HD and 7% with PD (U.S. Renal Data System, 2013). The renal disease continuum (Fig. 46-7) demonstrates the critical junctures in renal disease care extending from the early diagnosis to management of the patient on dialysis. Processes of care for each stage should be developed from evidence-based recommendations and linked to auditing tools that can provide organizations and health care teams ongoing feedback for optimizing results. The concept of RRT assignment in an integrated fashion is a key to prolonging ESRD survival. An integrated approach combining HD, PD, and renal transplant during the life of an ESRD patient may provide the best approach to optimizing survival. An integrated care approach whereby patients are started on PD and are transferred in a timely fashion to HD, when PD- or patient-related problems occur, demonstrates an increase in survival compared with those remaining on HD for their entire life span (Van Biesen et al, 2000). Box 46-10 indicates transition points that may stimulate transfer from one modality to another. RRT is preserved longer on PD than on HD. BP is better controlled, and ventricular arrhythmias are observed less often on PD than on HD. Weight gain and inadequate dialysis after 3 years are more common on PD than with HD. Although vascular access problems and hemodynamic instability are the most common reasons for transfer to PD from HD, other reasons include infection (peritonitis, catheter, tunnel infections), inadequate dialysis, and catheter malfunction. Quality guidelines are established for HD adequacy, PD adequacy, vascular access, anemia management, bone metabolism, and nutrition.

Hospitalization Risk in Chronic Kidney Disease/End-Stage Renal Disease

CKD patients are 10 times more likely to be hospitalized, and on average, hospitalization lasts 1 day longer compared with

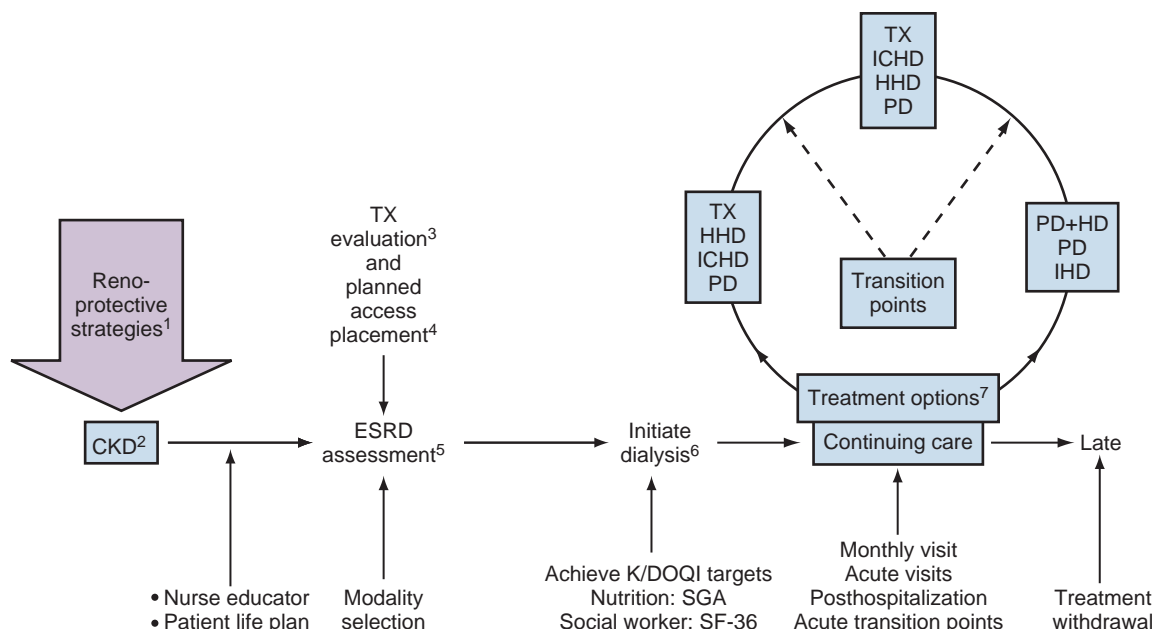

Figure 46-7. Kidney disease continuum. 1, Population screening (serum creatinine >1.2 mg/dL), delay progression (stages 1 and 2). 2, Preserve residual renal function (RRF), educate, and assess comorbidities (glomerular filtration rate [GFR] stages 3 and 4, and higher risk based on albuminuria score as well). 3, Preemptive transplant. 4, Peritoneal dialysis (PD)/hemodialysis modalities. 5, Evaluate complication/risk; RRF 15 to 29 mL/min/1.73 m²: prepare for renal replacement therapy. 6, Initiate dialysis, avoid uremic complications, define physician problem-based care (GFR stage 5: <15 mL/min/1.73 m²). 7, Integrate different therapies throughout time dependent on critical junctures to extend survival years and control comorbidities: malnutrition, uncontrolled blood pressure, inadequate solute/water removal, access failure, RRF preservation. CKD, chronic kidney disease; ESRD, end-stage renal disease; HHD, home hemodialysis; ICHD, in-center hemodialysis; IHD, intermittent hemodialysis; PD, peritoneal dialysis; SF-36, Short Form-36; SGA, subjective global assessment; TX, treatment.

BOX 46-10 Transition Points for Modality Transfers

PERITONEAL DIALYSIS TRANSFER TO HEMODIALYSIS

Recurrent infection
Catheter malfunction
Ultrafiltration failure
Adequacy (solute) failure
Psychological/cognitive burnout
Hospitalization/surgery
Uncontrolled diabetes
Hypotension

HEMODIALYSIS TRANSFER TO PERITONEAL DIALYSIS

Recurrent congestive heart failure
Vascular access failure
Hypercoagulability
Malnutrition
Intradialysis hypotension
Nursing home care

non-renal failure patients (Thamer et al, 1996). Hospital admissions for ESRD patients in the United States have remained relatively stable since 1993, and the number of hospital days has fallen 12% for HD patients, 16% for transplant, and 19% for PD patients. ESRD patients secondary to diabetes are admitted most frequently (U.S. Renal Data System, 2013). Inpatient hospital care

accounts for 41% of the total ESRD costs (Bruns et al, 1998). The most common causes of hospital admission in ESRD include infection and cardiovascular disease (U.S. Renal Data System, 2013). The total hospital discharges by general diagnostic-related group (DRG) charges from 1996 to 1998 for ESRD patients in the United States showed that the four most common causes for admission were circulatory (36.4%), renal system (15.6%), respiratory system (7.4%), and infection (5.7%) (Foley and Collins, 2007; Collins et al, 2009). The hospitalization rates for HD patients have increased 43% since 1993 with the major cause being infection (U.S. Renal Data System, 2013). Vascular catheter access remains an important source of risk. In the PD population, hospitalization rates and infection have remained stable. Patients undergoing RRT are often hospitalized with general medical problems, most often stemming from comorbid conditions. The length of stay for HD patients differed by the medical service to which they were admitted. Overall costs for hospitalization tended to be less on the nephrology service than on internal medicine service (6.3 days vs. 8.1 days) (Kshirsagar et al, 2000a). Total cost per admission was \$2848 more for an HD admit to internal medicine service versus nephrology service, and yet the risk of readmission was not significantly higher.

Rocco and colleagues identified specific risk factors for hospital use in chronic dialysis patients from a cohort of 1572 patients in Network VI (North Carolina, South Carolina, and Georgia). The strongest predictors of the number of hospitalizations per year of patients at risk included low serum albumin, decreased activity level, diabetes mellitus as a primary cause of ESRD, peripheral vascular disease, white race, increasing age, and congestive heart failure (Rocco et al, 1996). Both nutritional status (serum albumin, creatinine, transferrin, prealbumin, and lean body mass [bioelectric

TABLE 46-8 Defining Therapies for Acute Renal Failure in Patients with Chronic Kidney Disease

THERAPY	DEFINITION	INDICATION	MODALITY OPTION
Hemodialysis	Convective-based process across semipermeable membrane	Solute/H ₂ O removal Hyperkalemia	IHD, DHD, CAVHD, CVVHD
Hemofiltration	Convective-based solute removal with plasma water filtered across highly permeable membrane	Volume control, acid-base disorders, azotemia, congestive heart failure, multiorgan failure	IHD, CVVHD, CAVH
Hemodiafiltration	Convective and diffusive process across semipermeable membrane, increased small and large molecule removal	Acidosis, possible multiorgan failure, ARDS, dialysis instability	IHDF, CAVHDF, CVWHDF
Ultrafiltration	Plasma water removal, 2-5 L/24 hr	Fluid removal, congestive heart failure, total body anasarca, intubation or reintubation risk	SCUF, CVVUF, IUF
Sustained low-efficiency dialysis	Slow, convective-based process across semipermeable membrane	IHD treatment failure resulting from hypotension or inadequate clearance	SLED
Peritoneal dialysis	Diffusive and convective transport across peritoneal membrane	Azotemia, volume control, hypotension, without access to continuous hemodialysis treatments	CAPD, CCPD (APD)

APD, automated peritoneal dialysis; ARDS, acute respiratory distress syndrome; CAPD, continuous ambulatory peritoneal dialysis; CAVH, continuous arteriovenous hemofiltration; CAVHD, continuous arteriovenous hemodialysis; CAVHDF, continuous arteriovenous hemodiafiltration; CCPD, continuous cyclic peritoneal dialysis; CVVHD, continuous venovenous hemodialysis; CVWHDF, continuous venovenous hemodiafiltration; CVVUF, continuous venovenous ultrafiltration; DHD, daily hemodialysis; IHD, intermittent hemodialysis; IHDF, intermittent hemodiafiltration; IUF, intermittent ultrafiltration; SCUF, slow continuous ultrafiltration; SLED, sustained low-efficiency dialysis.

BOX 46-11 Proposed Criteria for Initiation of Renal Replacement Therapy

Oliguria (urine output <200 mL/12 hr)
 Anuria or extreme oliguria (urine output <50 mL/12 hr)
 Hyperkalemia ($[K^+]$ >6.5 mmol/L)
 Severe acidemia (pH <7.1)
 Azotemia ($[urea]$ >30 mmol/L)
 Clinically significant organ (especially lung) edema
 Uremic encephalopathy
 Uremic pericarditis
 Uremic neuropathy/myopathy
 Severe dysnatremia ($[Na]$ >160 or <115 mmol/L)
 Drug overdose with dialyzable toxin

From Bellomo R, Ronco C. Indications and criteria for initiating renal replacement therapy in the intensive care unit. *Kidney Int Suppl* 1998;66: S106-9.

impedance)] and inflammatory response (i.e., C-reactive protein [CRP]), are independent predictors of hospitalization in chronic HD patients (Ikizler et al, 1999).

Sarnak and Jaber demonstrated that mortality rates secondary to sepsis are onefold to several hundredfold higher in dialysis patterns (HD and PD) compared with the general population (Sarnak and Jaber, 2000). Renal transplant recipients have sepsis-associated mortality rates higher than the general population but lower than dialysis patients. Infection is the second leading cause of death in patients with ESRD. Acquired immune deficiencies with uremia, advanced age, and a broad array of comorbid conditions contribute to the observed infection risk and admission rate for kidney disease patients.

Acute worsening of renal function may occur in hospitalized CKD patients. The proposed criteria for initiation of RRT in this setting are listed in Box 46-11 (Bellomo and Ronco, 1998). For

ESRD patients undergoing high-risk surgery, sequential daily dialysis for 3 days preoperatively should be entertained to optimize fluid and to ensure stable serum potassium and solute levels.

In patients requiring RRT, aggressive volume and solute control are essential to achieve optimal postoperative recovery. Outpatient dialysis schedules may not meet the needs of in-hospital patients. Some individuals may require more intensive therapy either daily or continuously if they are hemodynamically unstable. A number of different therapies can be used to treat critically ill patients requiring RRT (Table 46-8). Hemodynamically unstable patients might not tolerate intermittent HD and require continuous venovenous hemodialysis.

Patients with serum albumin less than 3 g/dL with correspondingly low prealbumin values less than 25 g/dL should undergo enteral feedings or aggressive oral supplementation. TPN may be used if the gastrointestinal tract is nonfunctional. Aggressive ultrafiltration either alone or in conjunction with regular HD should be implemented to control edema and to decrease the risk for intubation or reintubation, congestive heart failure, and infectious-related complications.

CKD patients have a poorly responsive ventilator control system that impedes timely ventilator weaning (Seki et al, 1993). Therefore reintubation has a significantly higher morbidity and mortality in CKD and should be avoided. Other preventive strategies involve vaccinations (pneumococcus, influenza, hepatitis), hypertension control, identification of high-risk patients for congestive heart failure, early treatment of upper respiratory infection/bronchitis, and optimization of functional status (vision assessment, exercise, cognitive stability). Identifying patients with risk characteristics that lead to hospitalization and designing a management plan to modify risk are essential and deserving of further study.

KEY POINTS: CHRONIC RENAL FAILURE

- The NKF developed and published clinical practice guidelines for CKD in 2002 to diagnose and treat CKD and its comorbidities more consistently. These guidelines were updated by the KDIGO ([KDIGO Committee, 2013](#)). The classification of CKD now incorporates assessment of albuminuria besides GFR estimation. This better reflects the health implications of kidney diseases.
- At a set point (usually $\geq 50\%$ reduction in GFR), a relentless progressive loss of renal function ensues even when the initial insult becomes inactive—the hyperfiltration hypothesis.
- Progression of renal insufficiency involves hemodynamic and nonhemodynamic mechanisms.
- ACE inhibitors and ARBs are the most effective agents in slowing the progression of renal disease by both hemodynamic and nonhemodynamic mechanisms.
- The most common etiologies of CKD are diabetes and hypertension.
- Comorbidities associated with CKD need treatment to optimize survival and to diminish morbidity. This includes managing hypertension, blood lipids, smoking cessation, target weight, anemia, and glycemic control.
- A serious adverse advent, NSF, has been linked to gadolinium-based contrast agents.
- Major surgical interventions mandate thorough medical evaluation, particularly cardiovascular health.

Role of the Urologist in Renal Transplantation

End-Stage Renal Disease

Selection of Kidney Transplant Recipients

Selection of Kidney Transplant Donors

Kidney Transplant Operation

Post-transplant Care

Autotransplantation

ROLE OF THE UROLOGIST IN RENAL TRANSPLANTATION

The invention of renal replacement therapy is one of the major advances in 20th-century medicine. Dialysis treatments were initially indicated only for patients with acute kidney injury. In the first half of the century there were only short-term success and many technical failures with kidney transplantation. Through transplantation experiments in animal models many of the fundamentals of immunology were elucidated. During the Second World War the treatment of burns stimulated intense interest in skin grafting. A series of papers starting in 1944 by Peter Medawar clearly demonstrated the process of graft rejection, as well as the acceptance of tissue from the same individual or an identical twin. Moreover, elegant experiments demonstrated that rejection could be prevented by transfer of cells from the donor to the recipient during the neonatal period (Billingham et al, 1953). Advances in vascular surgical technique and tolerance induction renewed interest in organ transplantation. Urologists in France provided solutions to many of the technical barriers. A team of experts in basic science and clinical medicine led by John P. Merrill (nephrology), Joseph E. Murray (plastic surgery), and J. Hartwell Harrison (urology) at the Peter Bent Brigham Hospital performed the first successful kidney transplant between identical twins in December 1954 (Terasaki, 1991; Starzl, 1992).

Transplantation has evolved from an experimental procedure to the standard of care for many types of organ failure. The best outcomes are achieved with an integrated multidisciplinary team. Urologists will therefore continue to be called on to manage patients with organ transplants.

END-STAGE RENAL DISEASE

Incidence and Prevalence

In the 1960s dialysis was available in only a few centers and considered experimental by commercial insurance companies, but in the decades that followed, treatment options for patients with kidney failure improved dramatically. Passage of Medicare legislation in 1972 provided payment for renal replacement therapy (RRT), including maintenance dialysis and renal transplantation. In 2011 the number of patients receiving treatment for end-stage renal disease (ESRD) reached 615,899—a new high. The number of incident dialysis patients was 112,788, and 2855 patients received a preemptive transplant as their first ESRD treatment modality; thus a total of 115,643 patients began ESRD therapy in 2011—a level below that of the two prior years. The incidence of patients starting therapy on hemodialysis declined for the first time in more than three decades. The ESRD population initiated on peritoneal dialysis

now accounts for 6.6% of patients. The prevalence of ESRD included 430,273 patients on dialysis and 185,626 patients with a functioning kidney transplant, and the 1-year growth of 3.4 percent—to 615,899—was the smallest in 30 years (United States Renal Data System, 2013).

Treatment Options

Hemodialysis is usually performed in a center for 2.5 to 5 hours and three times per week. Blood is removed using a catheter in a central vein or large-bore needles inserted into an arteriovenous fistula/graft. Solutes are removed by diffusion across a semipermeable membrane. Fluid removal, also known as ultrafiltration, is controlled by regulating the hydrostatic pressure across the membrane. Patients often complain of nausea, muscle cramps, hypotension, and fatigue. Increasing the number of treatments per week and decreasing the rate of fluid removal may decrease symptoms, but is generally limited to those patients with a dedicated caregiver who can administer the treatment in the home. Permanent dialysis access using an arteriovenous fistula has the best patency rate and reduces the risk for hematogenous infection. Venous stenosis and eventual lack of vascular access is an increasingly recognized complication of prolonged dialysis using central venous catheters. If possible, a fistula should be created at least 6 months before the anticipated start of hemodialysis treatment. Peritoneal dialysis uses the fluid and solute transport characteristics of the peritoneum as an endogenous dialysis membrane. A Silastic catheter is surgically placed in the abdominal cavity, and the exit site is protected by a cuff embedded under the skin. After several weeks, 1500 to 3000 mL of sterile hypertonic solution flows into the abdomen and is allowed to dwell for a specified period to achieve the appropriate solute removal and ultrafiltration. The fluid is then discarded. The hypertonicity of the fluid is commonly obtained with glucose concentrations of 1.5% to 4.25%. This can deliver a significant caloric load and increase the risk for infection. To reduce this problem, solutions containing glucose polymers (e.g., icodextrin) have been introduced to decrease absorption of solute and increase ultrafiltration for a longer period. **Unfortunately, both icodextrin and maltose can cause falsely elevated glucose results with point-of-care devices, possibly leading to inappropriate therapy (Floré and Delanghe, 2009).** This procedure is typically done in the home by a machine that regulates the fluid flow while the patient sleeps (continuous cycling peritoneal dialysis) or periodic exchanges during the day (continuous ambulatory peritoneal dialysis). The advantages over hemodialysis include more stable blood pressure, solute removal, and promotion of patient independence. The major complications of peritoneal dialysis are bacterial peritonitis and peritoneal fibrosis.

Long-Term Complications of Dialysis

Patients with a chronic glomerular filtration rate (GFR) of less than 15 mL/min are classified as having stage 5 chronic kidney disease as defined by the National Kidney Foundation guidelines (see Chapter 46). Most patients with a GFR less than 10 mL/min are symptomatic and benefit from RRT. The decision to initiate therapy must be individualized based on patient preferences to provide the most quality-adjusted life years. As the waiting time for deceased-donor renal transplant increases, the long-term complications of dialysis may have a significant impact on the choice of renal transplantation as an appropriate treatment modality. A prolonged time on dialysis increases the risk for post-transplant morbidity and mortality.

Cardiovascular disease is prevalent in this population because hypertension and diabetes are the two most common causes of ESRD in adults. At the time of dialysis initiation, 50% to 80% of patients will have left ventricular hypertrophy, and the presence of coronary artery disease is 10- to 20-fold greater than in the general population. Patients over the age of 50 years have a 20% mortality rate during their first year of dialysis, and approximately half of the patients of this age with diabetes will die on dialysis after 5 years ([United States Renal Data System, 2013](#)). Blood pressure can be difficult to control in patients with limited kidney function. Oliguric patients are advised to limit fluid intake, leading to chronic thirst. The administration of erythropoiesis-stimulating agents has significantly reduced the need for blood transfusions, but anemia remains a common problem. Poor elimination of phosphorus by dialysis can lead to severe itching, conjunctival irritation, and alterations in bone metabolism. Hyperphosphatemia must therefore be regulated by dietary restriction and phosphate binders. Secondary hyperparathyroidism can lead to hypercalcemia. A syndrome characterized by vascular calcification, thrombosis, and necrosis known as calciphylaxis may occur if the serum calcium \times phosphorus product is greater than 60 mg²/dL². Phosphate enemas should not be administered to patients with ESRD to avoid this complication.

Hyperkalemia is also more common in ESRD and may require dietary restriction. If rapid correction is necessary, dialysis is the best option. Sodium polystyrene sulfonate in sorbitol administered either orally or per rectum may cause intestinal necrosis. The risk for this complication may be increased with impaired bowel function resulting from postoperative opioids or ileus ([Gerstman et al, 1992](#)).

Kidney transplantation is generally considered the optimal form of renal replacement therapy. Selecting the most appropriate therapy, however, must be individualized based on patient priorities and assessment of risks. Kidney transplantation should be viewed as another treatment for ESRD and not a cure. A detailed overview of the outcomes with kidney transplant in the United States is updated annually ([Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients, 2012](#)).

When compared to adults with ESRD, children are more likely to receive chronic peritoneal dialysis, and they are more likely to undergo renal transplantation ([United States Renal Data System, 2013](#)). There is a relatively greater availability of parental kidney donors, and children receive preferential priority when they are listed for deceased kidney transplantation. **Special problems in children with ESRD include limited dialysis access, growth failure, poor nutrition, and psychiatric problems.**

Results of Treatment

Data from the [U.S. Renal Data System \(2013\)](#) indicate that survival after renal transplantation is significantly better than that of patients treated with dialysis. Although this simply may mean that healthier patients are more likely to undergo transplantation, more controlled analyses have indicated a significantly reduced mortality risk for renal transplant recipients compared with acceptable transplantation candidates waiting on dialysis ([Meier-Kriesche et al, 2001](#)). Regardless of whether the treatment

modality is dialysis or transplantation, the major causes of death are, in order, heart disease, sepsis, and stroke ([United States Renal Data System, 2013](#)).

SELECTION OF KIDNEY TRANSPLANT RECIPIENTS

The goal of kidney transplantation is to improve patient survival and quality of life. The evaluation process is designed to estimate the risks and benefits of the various therapeutic options. The patient must be educated regarding the risks associated with their cause of renal failure and existing comorbidities, as well as the risk of the operative procedure and required immunosuppression. Individual estimates of patient and graft survival with various donor options should be discussed to maintain hope for a better future with realistic expectations.

Preliminary Screening

All dialysis centers in the United States are mandated to be associated with a transplant center, and all Medicare patients are legally entitled to a transplant evaluation. A preliminary screening process should identify absolute contraindications to transplantation and modifiable risk factors ([Fig. 47-1](#)). **Any patient with a GFR less than 20 mL/min should have the opportunity to meet with a transplant team to assess barriers to transplantation and potential donor options.** The transplant evaluation can be an opportunity to counsel patients and advocate for changes in lifestyle to promote health. Morbid obesity, defined as a body mass index greater than 35, is more prevalent in the dialysis population and is a significant overall risk factor ([Srinivas and Meier-Kriesche, 2013](#)). When increasing exercise and reducing caloric intake alone are not successful, surgical weight-loss treatment options should be considered. Adherence to medications, dietary recommendations, and physician appointments is critical to the success of transplantation. Missing dialysis treatments, serum phosphorus or potassium levels greater than 6 mg/dL, drug or tobacco use, and weight gain of over 3 kg between dialysis sessions should initiate appropriate consultations with physicians, social workers, and dietitians. Depression and other psychiatric illnesses can improve with proper treatment and are not absolute contraindications to transplantation. A person who can serve as a caregiver after transplantation must be identified and be included in the entire transplant process.

Cause of Kidney Disease

When kidney function is deteriorating, a biopsy provides the most definitive diagnosis. However, if patients present with small kidneys on renal ultrasound, then a biopsy will most likely show advanced fibrosis of unknown cause. A history of childhood enuresis or urinary tract infections (UTIs) may suggest unrecognized congenital disease. Patients with primary focal segmental glomerulosclerosis, hemolytic-uremic syndrome, membranoproliferative glomerulonephritis, and primary oxalosis should be informed of the significant risk for disease recurrence in the allograft. Before transplant, the rate of progression of the serum creatinine and proteinuria may help predict the risk for recurrence. Patients with primary oxalosis and other metabolic diseases may benefit from combined kidney and liver transplant. Patients with sickle cell disease, amyloidosis, and Fabry disease are also at increased risk for disease recurrence but still may benefit from transplantation compared to dialysis. Immunoglobulin A (IgA) nephropathy is a disease that commonly recurs in the transplant kidney yet rarely leads to graft failure. Hypertension and diabetes are the most common causes of renal failure in adults but generally take many years to show evidence of disease in the transplant. Autosomal dominant polycystic kidney disease (ADPKD), cystinosis, renal dysplasia, and Alport syndrome without anti-glomerular basement membrane antibodies are examples of renal diseases that do not recur in the transplanted kidneys.

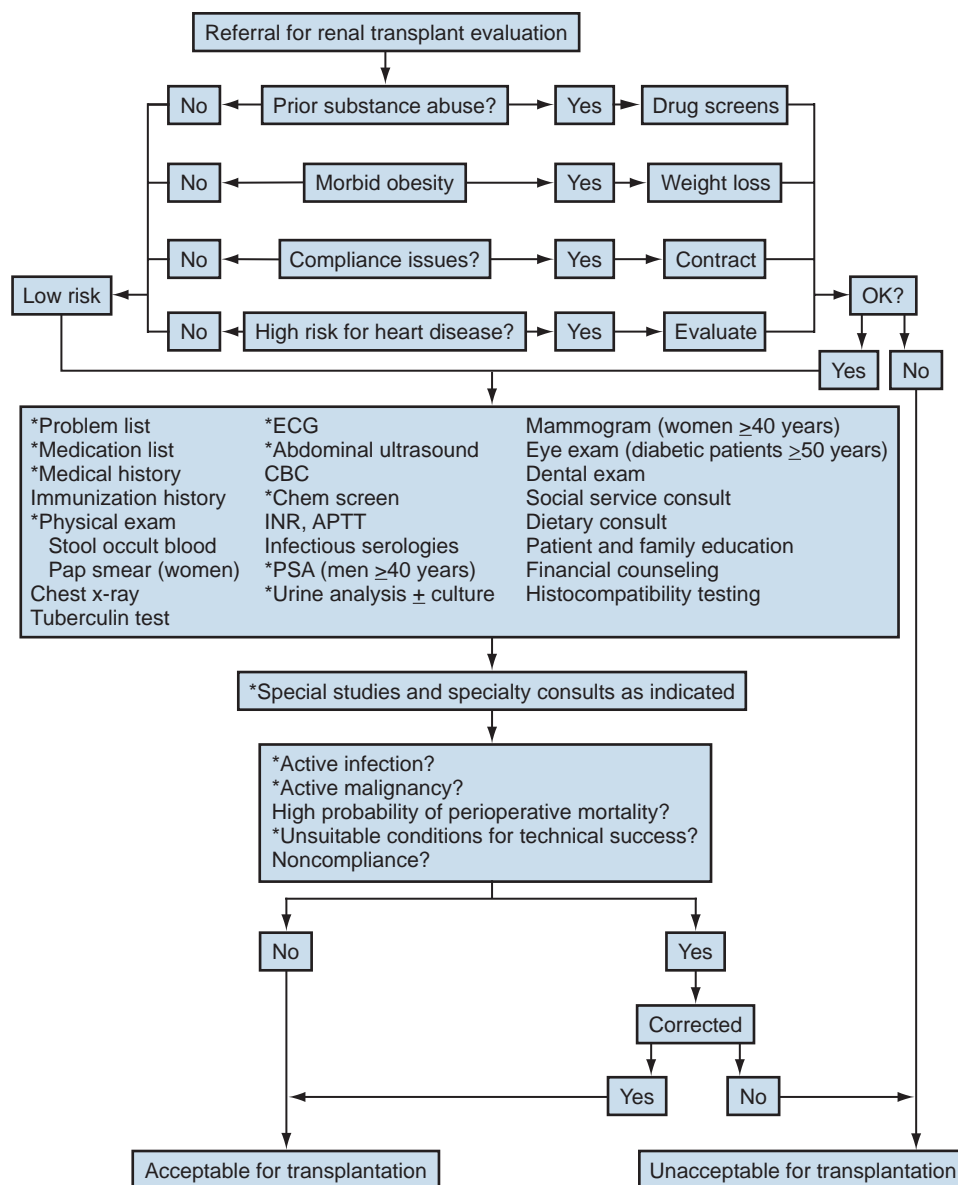

Figure 47-1. Algorithm for the evaluation of renal transplantation candidates. Circumstances may change the order in which data are obtained. APTT, activated partial thromboplastin time; CBC, complete blood cell count; ECG, electrocardiogram; INR, international normalized ratio; PSA, prostate-specific antigen. Asterisks indicate items of special significance for the urologist. (Modified from Barry JM. Current status of renal transplantation: patient evaluations and outcomes. *Urol Clin North Am* 2001;28:788.)

High Probability of Perioperative Morbidity or Mortality

Coronary artery disease is present in over 50% of patients with ESRD and may not manifest with typical symptoms. Periodic reevaluation for progression of disease is important because of the prolonged waiting time to receive a deceased-donor kidney (Lentine et al, 2012). Patients over the age of 50 years with coronary artery disease, cerebrovascular disease, congestive heart failure, diabetes, and renal failure have approximately a 25% risk for complications (Hoftman et al, 2013). Lack of mobility is a major risk factor, and simply walking with a patient for 100 yards can provide as much insight as other cardiac stress tests (McAdams-DeMarco et al, 2015). Most patients are screened with pharmacologic nuclear medicine cardiac imaging or echocardiograms to evaluate myocardial perfusion, ejection fraction, and valvular function. Abnormal cardiac testing should prompt referral to a cardiologist for further evaluation. Tobacco use is clearly linked with poor outcomes and

must be stopped. Any respiratory disease that requires home oxygen is a relative contraindication to transplantation. Patients with ADPKD who have a history of stroke or recurrent headaches, or a family history of stroke or cerebral aneurysm, should be screened for berry aneurysm of the cerebral arteries. Any history of prior severe infection should be investigated. Patients are screened for prior exposure to human immunodeficiency virus (HIV), hepatitis B and C, Epstein-Barr virus (EBV), and cytomegalovirus (CMV) in addition to syphilis and tuberculosis. The screening for endemic infections varies across countries and local regions. Infections should be treated or prevented with immunizations, but in most cases do not preclude transplantation.

Since the development of combination antiretroviral therapy, HIV infection has evolved into a chronic condition. Selected HIV-infected patients with ESRD are kidney transplant candidates if they do not have signs of opportunistic infection, the viral load is low, and adequate T lymphocyte counts are maintained (Stock et al, 2010).

Nonadherence

The success of any complex surgical procedure is highly dependent on the patient's motivation. Resolving barriers that impede a patient's understanding of and ability to follow postoperative instructions is crucial to the long-term success of transplantation. Interpreters, financial counselors, social workers, dietitians, pharmacists, and psychiatrists are critical team members. The patient and family members must actively be engaged in working toward a better state of health. Patients with chronic illnesses may develop abnormal coping mechanisms, including overeating, lack of exercise, depression, and chemical dependence. These conditions should be identified and corrected if possible. Like many of the other diseases associated with renal failure they should be viewed as risk factors and not absolute contraindications to transplantation.

Malignancy in Transplant Candidates

Patients with renal failure have a relative risk for cancer of approximately 1.18 compared to the general population (Maisonneuve et al, 1999). The highest cancer incidence was in patients younger than 35 years of age, with a decreasing incidence with increasing age. This may be due to genetic influences, environmental exposure, inability to remove certain toxins, virus infections, or reduced immune function. Patients with invasive or metastatic malignancy have the greatest risk for recurrence, and a 5-year disease free waiting period is generally recommended before the initiation of the immunosuppression required for transplantation. Melanoma has a very high risk for recurrence, and at least a 5-year wait is advised, whereas most other skin cancers are not a contraindication. The prognosis for the treatment of many cancers continues to improve as better diagnostic tests and therapies are developed. An oncology consultation should be obtained to determine the risk for recurrence, recommended surveillance, and long-term prognosis based on pathologic grade and stage of tumor. Molecular markers continue to improve the classification of many cancers to optimize therapy.

The screening tests for malignancy in transplant candidates are the same as the general population except for an ultrasound. Abdominal ultrasonography is indicated for the evaluation of renal failure, and the results should be reviewed during the transplant evaluation to assess for conditions that may be indicative of urologic disease. The incidence of acquired cystic disease increases progressively with duration of dialysis, and up to 80% are affected after 10 years on dialysis (Ishikawa et al, 2010). Cholecystectomy is recommended for patients with gallbladder polyps greater than 1 cm in diameter, and also in patients with diabetes and gallstones because of the increased morbidity associated with acute cholecystitis after transplantation (Benjamin et al, 2009). If the risk for elective cholecystectomy is high, we do not require this procedure for listing the candidate.

Urologic Malignancy in Transplant Candidates

The best treatment of prostate cancer is determined by grade, stage, estimated longevity, and patient preference. Low-risk prostate cancer should not be considered a contraindication to transplantation because in most cases the morbidity and mortality of having ESRD is greater. Patients who have low-risk disease felt to be amenable to active surveillance should be considered candidates for transplantation as long as they adhere to their surveillance regimen. Transplant candidates with a diagnosis of intermediate- or high-risk prostate cancer need to undergo definitive treatment to be considered a kidney transplant candidate. Those patients who have undergone treatment, typically radical prostatectomy or radiation, can be evaluated for transplantation as soon as they have recovered from their treatment. Waiting time after prostate cancer treatment should be dictated by the expected survival and probability of prostate cancer recurrence after treatment. Nomograms, such as those developed by Kattan and colleagues, are useful for predicting such parameters and

are easily accessible online (<http://nomograms.mskcc.org/Prostate/index.aspx>). It is important to remember that even patients with fairly high-risk features have a low chance for disease recurrence or death from prostate cancer after treatment. For example, a 55-year-old with Gleason 4 + 4 disease with a preoperative prostate-specific antigen (PSA) of 20, can expect an 82% chance for progression-free survival at 10 years if the PSA is not detectable 2 years after treatment. We therefore find it reasonable in most intermediate- to high-risk cases to wait 1 to 2 years before transplantation. Patients who have adverse pathologic features such as positive lymph nodes or seminal vesicle involvement have lower expected survival and demand longer follow-up, usually 5 years.

Asymptomatic microscopic hematuria should be evaluated in patients with renal failure according to the American Urological Association (AUA) guidelines (Davis et al, 2012). The risk for both kidney (standardized incidence ratio [SIR] 3.6; confidence interval [CI] 3.5 to 3.8) and bladder (SIR 1.5, CI 1.4 to 1.6) cancer is increased with renal failure (Stewart et al, 2003). Renal cysts in patients with chronic kidney disease may become infected, bleed, or undergo malignant transformation. Complex cysts should be monitored with serial imaging and may be an indication for pre-transplant nephrectomy if the urine output is limited. Small, low-grade superficial (Ta) transitional cell cancer has a low risk for progression and is not a contraindication to transplantation with appropriate surveillance. Aristolochic acid, a Chinese herb used to treat labor pains and found in some weight loss remedies, has been associated with ESRD and upper tract transitional cell carcinoma. This also may be the agent responsible for Balkan nephropathy (Olivier et al, 2012). Patients with a history of exposure to solvents, tobacco, cyclophosphamide, chronic infection, or irritative voiding symptoms should have bladder wash cytology because of the increased risk for urothelial carcinoma. Patients with positive cytologic findings or high-grade or invasive tumors should have a 5-year cancer-free interval before initiation of immunosuppression to reduce the risk for tumor recurrence and progression. In situ and all noninvasive papillary tumors of the bladder do not require a waiting period (Penn, 1993). Asymptomatic renal masses are frequently detected by imaging to evaluate renal insufficiency. Approximately 20% of renal masses less than 3 cm in diameter are benign and the risk for metastasis is very low. These tumors should not limit access to transplantation. The treatment of clinical stage 1 renal tumors should be individualized as recommended by the AUA guidelines. **Active surveillance or localized therapy for urologic malignancy, with appropriate indications and patient compliance, should be considered as adequate treatment before transplantation.**

Surgical Evaluation

Preparation of a patient for kidney transplantation requires a careful assessment of the peripheral vascular system. Symptoms of claudication or rest pain should be elicited, as well as the risk factors for vascular disease. Any prior vascular surgery must be documented, particularly endovascular procedures, which are becoming more common. The character of pulses, particularly in the femoral area, should be documented. Unless evidence exists of extensive calcification or bruit, additional vascular studies are rarely necessary. However, Doppler flow ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), or angiography may be necessary to evaluate flow-limiting lesions or extensive calcification. Iodinated contrast can be nephrotoxic and must be used with caution in patients with marginal renal function. Hydration and diuresis appear to be the most effective ways to minimize the risk for renal injury. Gadolinium contrast agents have been associated with nephrogenic systemic fibrosis in some patients with marginal renal function (Chang et al, 2013). The risk is greatest for patients on dialysis. Selective angiography with carbon dioxide gas or MRI with intravenous (IV) iron contrast may be indicated in some cases to avoid nephrotoxicity.

Nephrotic syndrome can lead to a hypercoagulable state with loss of natural anticoagulants antithrombin III, protein C, and

protein S. Renal transplant recipients have an elevated risk for deep vein thrombosis and graft thrombosis when there is a history of previous dialysis access failure, miscarriage, antiphospholipid antibody syndrome, or hyperhomocysteinemia. Homozygous mutations of the methylenetetrahydrofolate reductase (*MTHFR*) gene can lead to impaired folate metabolism and hyperhomocysteinemia, which has been associated with accelerated atherosclerosis. Patients can be screened for thrombophilia by checking clotting factors, including the platelet count, prothrombin time, partial thromboplastin time, and activated protein C resistance ratio (factor V Leiden mutation).

Urologic Procedures in Renal Transplant Candidates

During the renal transplant evaluation process, potential recipients may be diagnosed with a number of urologic conditions that require intervention. Many patients with ESRD have minimal urine output that can mask abnormal bladder function. The preoperative history should review prior episodes of UTI, hematuria, urolithiasis, enuresis, incontinence, retention, and voiding dysfunction. The details of previous abdominal or pelvic surgery could have a significant impact on the optimal placement of a renal allograft. Prior pelvic radiation can inhibit bladder function and wound healing. The physical examination should include descriptions of scars, catheters, and stomas. Additional urologic studies may be indicated to evaluate the anatomy of the urinary tract, bladder function, and risk for malignancy (Table 47-1). In patients on peritoneal dialysis, fluid in the pelvis can be misinterpreted as residual urine. If patients have an inflatable penile prosthesis with an abdominal reservoir, it can be mistaken for the urinary bladder or make exposure of the bladder more challenging.

Indications and Timing of Native Nephrectomy

Preservation of residual renal function for patients on dialysis can limit the need for fluid and dietary restrictions. It also may improve the management of hypertension and reduce the risk for cardiac complications (Shemin et al, 2001). Therefore the indication for native nephrectomy must be balanced by the risk of observation. The most common indications for native nephrectomy are outlined in Box 47-1.

If the potential recipient has a living donor, it is ideal to perform nephrectomy at least 6 weeks before the scheduled transplant. However, if the patient is not on dialysis, it exposes the patient to the infectious risks and complications of dialysis. Some surgeons prefer to do the nephrectomy at the time of transplant, but this may increase the risk for complications with the transplant kidney. For patients who do not have a living donor, the timing of pretransplant nephrectomy should be based on the indication, residual urine output, and accumulated wait list time. Patients who have adult polycystic kidney disease (PKD) may require unilateral or bilateral native nephrectomy before transplantation if there is concern for malignancy, recurrent infection, intractable gross hematuria, or continued discomfort because of size. Patients who may undergo transplantation before the start of dialysis may benefit from post-transplant nephrectomy. Asymptomatic patients with severely enlarged kidneys may require native nephrectomy to make room for the renal allograft. Adequate space in the iliac fossa can generally be assessed by a combination of physical examination and abdominal imaging. If the enlarged kidney is not palpable inferior to the anterior superior iliac spine, there usually is room for a renal allograft, but this decision is ultimately made by the transplant surgeon. Nephrectomy can be performed concurrently with the renal transplant, but this may increase perioperative complications and morbidity (Fuller et al, 2005). Chronically infected kidneys should be removed, but uninfected asymptomatic urinary stones do not require treatment. Transplant candidates with a history of vesicoureteral reflux (VUR) require native nephrectomy only if the VUR is associated with recurrent urinary infections.

TABLE 47-1 Recommendations for Additional Urologic Studies in Renal Transplant Candidates

STUDIES	INDICATIONS
Voiding cystourethrogram ± urodynamics	Voiding dysfunction, history of pyelonephritis or reflux, inconclusive ultrasonography
Cystoscopy	Suspected lower urinary tract cancer or planned invasive prostate therapy
Retrograde pyelography	Planned orthotopic renal transplantation or inconclusive ultrasonography
Abdominal computed tomography scan	Inconclusive ultrasonography for stone or mass, autosomal dominant polycystic kidney disease to accurately size kidneys
Urine or bladder wash cytology	Prior cyclophosphamide therapy or significant irritative voiding symptoms
Bladder biopsy	Suspected bladder fibrosis or cancer
Retrograde loopogram	Intestinal conduit
Retrograde pouchogram	Intestinal or gastric reservoir

Modified from Barry JM. Current status of renal transplantation: patient evaluations and outcomes. *Urol Clin North Am* 2001;28:677.

BOX 47-1 Recommendations for Pretransplant Nephrectomy

Symptomatic renal stones not cleared by minimally invasive techniques or lithotripsy
 High-grade solid renal tumors with or without acquired renal cystic disease
 Polycystic kidneys that are symptomatic, extend below the iliac crest, have been infected, or have solid tumors
 Persistent anti-glomerular basement membrane antibody levels
 Significant proteinuria not controlled with medical nephrectomy or angioablation
 Recurrent pyelonephritis
 Grade 4 or 5 vesicoureteral reflux with urinary tract infections

Treatment of Bladder Outlet Obstruction

Medical management of prostate hypertrophy in potential recipients with α -adrenergic blocking agents and 5 α -reductase inhibitors is preferred. In some cases a less selective α -blocker also will be beneficial in the treatment of hypertension. Patients with residual urine output who fail conservative treatment may be treated with modalities such as transurethral resection of the prostate (TURP) or laser vaporization (Volpe et al, 2013). Caution is advised in performing transurethral resection in anuric patients because of the high risk for bladder neck contracture or prostatic fossa strictures.

Urinary Diversion and Bladder Augmentation

Renal transplant recipients should have an established urinary drainage system because cutaneous ureterostomy has a high risk for stenosis and infection. Prolonged percutaneous drainage is prone

to repeated infection with increasingly resistant organisms. Ideally the urinary reservoir should have a capacity of at least 200 mL, low storage pressure, an antirefluxing ureteral anastomosis, and the ability to empty completely.

Patients with prolonged anuria may lose bladder capacity, but even small defunctionalized bladders will frequently regain normal volume within weeks of transplantation (Wu et al, 2008). The timing of bladder surgery must be coordinated with the transplant operation. In general, reconstructive procedures involving bowel are not performed simultaneously because of the increased risk for infection and poor wound healing associated with maximal immunosuppression. However, experience with simultaneous kidney and pancreas transplant using enteric drainage demonstrates that bowel surgery is not absolutely contraindicated. Lower urinary tract reconstruction is best done with adequate urine production to reduce the risk for stricture, stones, infection, and loss of compliance. A urothelium-lined augmentation is preferred because mucus does not need to be rinsed from the reservoir on a regular basis. If the reservoir does not empty completely, patients must be taught the technique of clean intermittent catheterization. It is critical that patients and their caregivers understand that renal transplantation will not improve bladder function. They must be aware of potential complications associated with abnormal bladder function but should not be discouraged from transplantation, because longevity and quality of life can be significantly improved (Sager et al, 2011).

SELECTION OF KIDNEY TRANSPLANT DONORS

As soon as a patient is deemed to be an acceptable kidney transplant candidate, the search for a suitable kidney donor is initiated. The recipient is encouraged to bring potential living kidney donors to educational seminars. Renal transplant outcomes are significantly improved with a living compared to a deceased donor. The ultimate pairing of a kidney donor with a recipient is a complex process that involves both immunologic and nonimmunologic factors.

Deceased Donor Allocation and Selection

While potential living kidney donors are evaluated, suitable candidates are consented for kidneys from deceased donors. The Organ Procurement and Transplantation Network (OPTN) was established by the United States Congress under the *National Organ Transplant Act* of 1984. The Act called for the network to be operated by a private, nonprofit organization under federal contract. All U.S. transplant centers and organ procurement organizations (OPOs) must be members of the OPTN to receive funds through Medicare. Other members of the OPTN include independent histocompatibility laboratories and relevant medical, scientific, and professional organizations. Members of the OPTN must report data to the Scientific Registry of Transplant Recipients (SRTR). The primary goals of the OPTN are to (1) increase the effectiveness and efficiency of organ sharing and equity in the national system of organ allocation and (2) increase the supply of donated organs available for transplantation. The United Network for Organ Sharing (UNOS) administers the OPTN under contract with the Health Resources and Services Administration of the U.S. Department of Health and Human Services.

Declaration of Donor Death

As a requirement for participation in Medicare, all hospitals must report potential deaths to the local OPO. Organ procurement personnel screen all eligible donors and assign a staff member to discuss organ donation with the next of kin. Many states now have electronic donor registries and the option to give consent for organ donation with a driver's license. An extensive questionnaire, clinical history, physical examination, and laboratory tests, including assays for syphilis, hepatitis, HIV, and human T-lymphoproliferative virus, are obtained to evaluate the risk for transmissible infection and malignancy. The declaration of donor death must be made by two

BOX 47-2 Guidelines for the Determination of Death by Neurologic Criteria

- I. Complete cessation of all brain and brain stem function
 - A. Coma as evidenced by no eye opening and no response to pain other than spinal cord reflexes
 - B. Absent brain stem reflexes
 1. Pupillary reflex
 2. Oculocephalic reflex ("doll's eyes")
 3. Oculovestibular reflex
 4. Corneal reflex
 5. Oropharyngeal reflex (gag and cough)
 6. Respiratory (apnea) challenge
- II. Apnea challenge
 - A. Preoxygenate patient with 100% oxygen for roughly 10 minutes and allow PaCO_2 to normalize to 40 mm Hg
 - B. Disconnect ventilator and place large-bore catheter down the endotracheal tube to deliver 100% O_2 or place on continuous positive airway pressure with 100% O_2
 - C. Observe patient for spontaneous breaths for approximately 10 minutes
 1. Obtain arterial blood gas (ABG) sample at that time and continue the test
 2. If no spontaneous breaths and a PaCO_2 below 60 mm Hg or 20 mm Hg above the patient's baseline, repeat ABG tests until PaCO_2 meets criteria
 - D. Positive test: No spontaneous breaths with an arterial PaCO_2 60 mm Hg or greater or 20 mm Hg above the patient's baseline confirms diagnosis of brain death
- III. Complete loss of brain and brain stem function must be irreversible
 - A. Establish cause of coma
 - B. Exclude complicating conditions
 1. Pharmacologic and metabolic intoxication
 2. Hypothermia
 3. Shock
 - C. Appropriate period of observation before second clinical examination
 1. 48 hours in infants up to 2 months of age
 2. 24 hours in those between 2 months and 1 year of age
 3. 6 to 12 hours in children older than 1 year of age
 4. 6 hours in adults older than the age of 18 years
- IV. Confirmatory tests (electroencephalogram, cerebral angiography, nuclear medicine brain scan)
 - A. Mandatory if unable to satisfy criteria or if any doubt exists
 - B. May shorten the period of observation, particularly in children and young adults
 - C. May help family members understand and accept the diagnosis

From Morenski JD, Oro JJ, Tobias JD, et al. Neurologic criteria for death. *J Intensive Care Med* 2003;18:211.

physicians who are not part of the organ recovery or transplantation team, to avoid any conflict of interest. Donors may be declared dead by neurologic criteria or cardiorespiratory criteria. Neurologic criteria for brain death include coma, irreversibility, known brain damage, and absence of brain stem reflexes (Box 47-2). Electroencephalography or brain blood flow imaging is not required but may be used to confirm the diagnosis at the clinician's discretion. In donors who are declared brain dead, cardiopulmonary function can be supported through the organ recovery process to minimize warm ischemia to the potential allografts.

Donation after circulatory death (DCD) typically occurs when a potential donor does not meet brain death criteria despite being comatose and ventilator dependent. In this situation, an individual or family may consent for donation only when death is determined by cessation of cardiopulmonary function. When the decision to withdraw care is made, ventilator support is discontinued in the intensive care unit or operating room. Death is declared by absence of spontaneous respiration and sustained asystole for 5 minutes before organ recovery begins. All DCD donor organs are subject to a variable period of warm ischemia depending on the specifics of the organ recovery.

Most deceased donors are suitable for multiple organ donation. To optimize the recovery of both thoracic and abdominal organs, a median sternotomy and midline incision are used for wide exposure. The organs are quickly inspected for signs of disease. Vascular control is established above and below the organs to be removed. Cannulas for the administration of preservation solution are inserted into the aorta, clamps are applied, venous effluent is vented, and the organs are flushed, immediately cooled with ice cold saline slush, carefully separated, inspected, and packaged for transportation. Spleen and lymph nodes are removed for histocompatibility testing, and iliac vessels are removed for vascular reconstruction of pancreas and liver grafts.

Kidney Preservation

The renal tubular sodium-potassium pump is required to maintain a high intracellular concentration of potassium. This pump depends on adenosine triphosphate (ATP) and uses oxidative phosphorylation to prevent passive diffusion of water into the cells. Ischemia leads to a depletion of ATP, loss of cellular potassium and magnesium, increased calcium, anaerobic glycolysis with acidosis, and activation of lysosomal enzymes. This leads to cell swelling and acute tubular necrosis.

After kidney transplant reperfusion, oxygen delivery recovers. Hypoxanthine, a product of ATP metabolism, is oxidized to xanthine with the formation of free radicals that cause further cell damage. Cellular swelling reduces perfusion, which leads to delayed function of the allograft and increased immunogenicity.

The goal of organ preservation is to maintain intracellular physiology. Tissues more than a few millimeters in thickness cannot be safely frozen because of the expansion of intracellular water. Hypothermia (4° C) reduces cellular energy requirements and preservation solutions are designed to maintain intracellular electrolyte composition (Table 47-2). Simple cold storage is inexpensive and facilitates the transportation of the donor kidney. Pulsatile preservation pumps may reduce vascular spasm, extend the preservation

time, and reduce the need for dialysis after transplant (Opelz and Döhler, 2007). In general, both the warm and cold ischemia times should be minimized to promote recovery of the allograft.

Allocation

The number of patients listed for kidney transplantation continues to expand disproportionately to the number of kidney transplantations performed annually. There are currently more than 99,000 patients waiting for deceased-donor kidney transplants, and with about 11,000 deceased-donor kidney transplantations performed annually, there are nine times as many patients with ESRD waiting as there will be deceased donor kidneys available in the coming year (United Network for Organ Sharing, 2014a). The inadequate supply of deceased-donor kidneys is one of the factors that have increased the use of “marginal” deceased-donor organs and the number of living donor kidneys in the past decade. The increase in living renal donation has been further facilitated by the widespread adoption of minimally invasive donor nephrectomy techniques; acceptance of living, biologically unrelated renal donors; and the development of protocols for transplantation across alloantibody barriers, including ABO blood group incompatibility.

The organ allocation policies continue to be revised based on analysis of data collected by the SRTR and approval of the UNOS Board of Directors. A schematic of the current UNOS allocation policy is available at the SRTR website (United Network for Organ Sharing, 2014c). In 2013 the allocation system had four categories of kidney donors: (1) standard criteria donor (SCD) younger than 35 years of age, (2) SCD older than 35 years, (3) expanded criteria donor (ECD), and (4) donation after circulatory death (DCD). Multiorgan transplant recipients, pediatric candidates, and former living kidney donors receive priority. For most kidney transplant candidates, however, the most important factor in receiving an organ offer is time spent on the waiting list. Additional factors that may give a potential recipient more points include the quality of the human leukocyte antigen (HLA)-DR match, and high levels of HLA antibodies (>80% panel reactive antibody [PRA]).

Because there is a wide range of potential kidney donors in terms of age, state of health, determination of death, and social history, there are different categories of deceased-donor kidneys that need to be discussed with potential recipients at the time of being added to the waiting list. The category of donor organs any recipient is willing to accept must be decided by the patient and transplant physician.

SCDs are younger than 60 years of age and do not meet any of the criteria for being an ECD. ECD donors are those who are over the age of 60 or those who are between the ages of 50 and 59 with two or more risk factors such as death from a stroke, hypertension, or elevated creatinine just before organ recovery (1.5 mg/dL). ECD organs have a 2-year graft survival of 80% versus 88% for an SCD organ (Pascual et al, 2008). DCD kidneys are subject to varying lengths of warm ischemia time and are thus susceptible to delayed graft function, but long-term graft survival is comparable to that of SCD kidneys (Snoeijs et al, 2010). Depending on size, pediatric donor kidneys may be transplanted en bloc, or, if large enough, split and allocated to two recipients. Recipients of pediatric donor kidneys should ideally be less than 80 kg, and some programs prefer not to use small kidneys in highly sensitized patients, but strategies vary across programs. If a particular donor's kidneys are felt to be suboptimal for transplantation into two recipients, they may be offered as dual adult donor kidneys. Patients who are deemed appropriate for ECD organs may be good candidates for dual adult kidney transplantation. UNOS implemented a new policy for deceased donor kidneys in December 2014. The goal is to allocate kidneys with the longest expected graft survival, estimated by the kidney donor profile index (KDPI), to patients with the longest estimated post-transplant survival, and increase the access to transplantation in patients with increased levels of anti-HLA antibodies (United Network for Organ Sharing, 2014b). A

TABLE 47-2 University of Wisconsin Preservation Solution Contents

K ⁺ lactobionate	100 mM
KH ₂ PO ₄	25 mM
MgSO ₄	5 mM
Raffinose	30 mM
Adenosine	5 mM
Glutathione	3 mM
Insulin	100 U/L
Dexamethasone	8 mg/L
Allopurinol	1 mM
Hydroxyethyl starch	50 g/L
Penicillin	200,000 U/L
pH	7.45
Potassium concentration	120 ± 5 mM
Sodium concentration	30 ± 5 mM
Osmolarity	320 ± 5 mOsm/L

KDPI of more than 85% is roughly equivalent to the previous ECD kidney.

Patients with ESRD who have hepatitis C virus (HCV) infection can be transplanted with kidneys from donors who are also HCV positive. Such recipients should have detectable HCV viral load and no evidence of cirrhosis. The Centers for Disease Control and Prevention reviewed the risk for transmission of viral diseases with organ transplantation ([Centers for Disease Control and Prevention, 1994](#)). It is important to note that all donor organs, even those not considered higher risk by the Centers for Disease Control and Prevention, have the potential to transmit disease. The Public Health Service (PHS) developed guidelines to educate patients about these risks. Patients must provide written permission to receive organs from donors considered higher risk (e.g., men who have had sex with another man in the preceding 5 years, users of nonmedical IV drugs, individuals who have received money for sex or have paid for sex in the preceding 5 years, and inmates of correctional facilities) ([Public Health Reports, 2013](#)). In most cases the risk for ESRD is far greater than the risk for infection.

ABO Blood Groups

The ABO blood group system describes antigens, which are carbohydrates expressed on the surface of red blood cells. Within the first 2 years of life, most individuals have been exposed to the noninherited antigen (probably via the digestive tract) ([Auf der Maur et al, 1993](#)). An individual who is blood type B, for instance, has developed anti-A antibody and thus will react to blood type A. Patients who are blood type O have both anti-A and anti-B antibodies and generally can receive only blood and/or allografts from blood type O donors. If a kidney is transplanted between ABO-incompatible individuals, antibodies will bind to the noninherited carbohydrate antigens expressed on endothelial cells, leading to activation of the complement cascade, coagulation, thrombosis, and rapid graft loss. However, if these antibodies have a low titer at the time of transplantation and production of antibody can be limited with immunosuppressive medications, then ABO incompatible renal transplants have been achieved ([Toki et al, 2009](#)). Most of these recipients develop “accommodation” to the donor antigen, despite persistent donor-specific blood type antibody. The graft endothelial antigen expression appears to be downregulated, and chronic complement activation is minimal.

Histocompatibility

The human major histocompatibility complex (MHC) is a cluster of more than 200 genes on chromosome 6p21.31 and is responsible for HLAs that are expressed as cell surface proteins on the renal allograft. It is these glycoprotein HLA molecules that are recognized by the recipient's leukocytes, which in turn trigger the immune response. Although the MHC is a major immunologic barrier to transplantation, it serves the important function of protecting the host from pathogens. A series of international workshops led to the nomenclature of the highly polymorphic HLA antigens. They are subdivided into class I (HLA-A, HLA-B, and HLA-C), class II (HLA-DR, HLA-DQ, and HLA-DP), and HLA class III, but only class I and II are currently used in the allocation of kidneys to recipients. **HLA class I genes are expressed by all nucleated cells. HLA class II genes are expressed by antigen-presenting cells (dendritic cells, monocytes, macrophages, and B-lymphocytes) and inflamed tissues, including endothelial cells.**

A recipient with mismatched (unshared) HLA antigens in the donor is at risk for development of antibody and cellular rejection. HLA antibodies may be formed by the recipient before transplantation as a result of pregnancies, previous transplants, blood transfusions, and possibly some infections. Individuals with antibodies directed at 20% of the population are said to be sensitized; those with antibodies to 80% of the population are considered highly sensitized. Sensitized transplant candidates, particularly those who are highly sensitized, may face extreme difficulty in finding a donor to whom they will have a negative crossmatch.

Crossmatch Techniques

Organs transplanted between genetically different individuals will be rejected without immunosuppression. Predicting the risk for a particular recipient rejecting a kidney from a given donor is very important. The ability to determine a positive crossmatch traces back to the work of Terasaki in the 1960s ([Terasaki and McClelland, 1964](#), [Patel and Terasaki, 1969](#)). The least sensitive test is the complement-dependent lymphocytotoxicity (CDC) assay in which donor T (class I antigens) or B lymphocytes (class I and II antigens) are combined with recipient serum, complement is added, and cell lysis is detected by dye exclusion after a period of incubation. The CDC crossmatch detects only high levels of HLA antibodies, so a positive CDC crossmatch is generally considered a contraindication to transplantation with that particular donor.

More sensitive crossmatch techniques that are able to detect lower levels of HLA antibodies also are employed, including the flow cytometry crossmatch (FCXM) and solid-phase single-antigen bead test (SAB). The FCXM is performed separately for both T and B cells, and each histocompatibility laboratory sets channel shift levels they consider being positive. Because the FCXM detects low levels of circulating antibodies, a positive crossmatch is not typically associated with hyperacute rejection, as seen with a positive CDC, but may be associated with higher rates of early rejection and lower graft survival. Some centers will proceed with transplantation using higher levels of immunosuppression despite a positive FCXM, particularly in broadly sensitized patients. A FCXM can detect non-HLA antibodies that are common in patients with autoimmune diseases. These antibodies are not associated with allograft rejection, and the false-positive test result can be eliminated by briefly incubating the donor cells with pronase (a proteolytic enzyme that removes non-HLA surface peptides).

The assays described can be used preoperatively to determine the percentage of donors with whom the recipient is likely to have a positive crossmatch. For the CDC or FCXM, the potential recipient's serum is tested with a panel of target cells comprising representative donor lymphocytes. The percentage of donors that cause a positive crossmatch is known as the PRA. For example, a potential recipient with a PRA of 80% is likely to have a positive crossmatch with 80% of the donor population.

Solid-phase assays that use purified HLA SABs allow for specific identification of circulating HLA antibodies. The recipient serum is incubated with the antigen beads and anti-human IgG is added, allowing for the bound antibody to be measured, usually by flow cytometry. The strength of a specific antibody is then reported as fluorescence intensity. The information from SAB testing can be used to perform what is known as a virtual crossmatch. Because a given donor's HLA typing will be known, the recipient's SAB testing may be employed to identify any donor-specific antibodies (DSAs) without having the donor cells. For example, if a potential recipient is found to have strong DSA to HLA-A2 and HLA-DR17, a center may choose to consider A2 and DR17 “unacceptable” in the UNOS database and kidneys from donors with this HLA phenotype will not be offered to the patient. The frequency and ethnic distribution of the HLA antigens in the donor population are monitored. Based on the results of specific HLA antibodies, a PRA can be calculated (cPRA) ([Cecka et al, 2011](#); [Health Resources and Services Administration, 2014](#)). Antibodies reactive to common antigens can significantly prolong the waiting time to find a suitable donor. The virtual crossmatch also has become important in living-donor kidney transplantation accomplished through kidney paired donation (KPD) when donors and recipients are frequently at different transplant centers.

Living Donor Evaluation

Individuals who would like to donate a kidney must undergo an intensive evaluation by a multidisciplinary team before being deemed a suitable donor ([Delmonico, 2005](#)) ([Fig. 47-2](#)). It is preferable that a physician who is independent of the transplant team act as an advocate for the potential donor. The medical evaluation

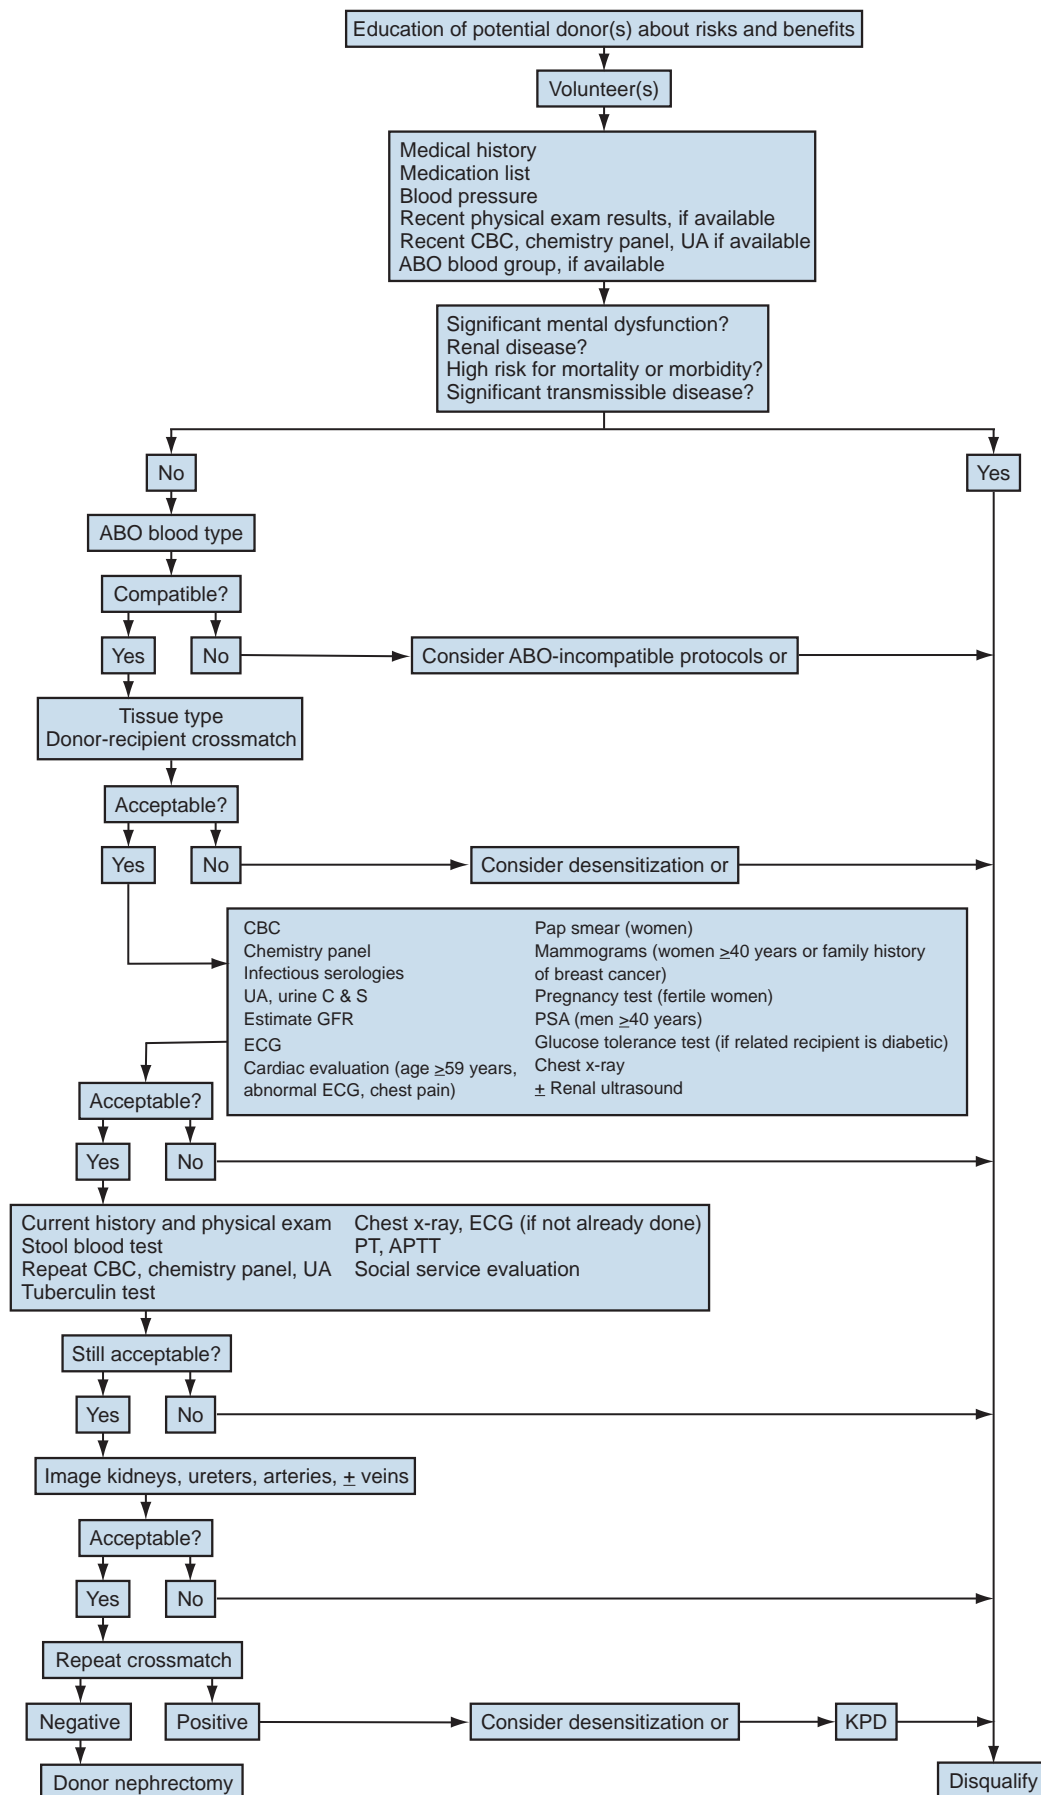

Figure 47-2. Algorithm for the evaluation of living renal donors. APTT, activated partial thromboplastin time; CBC, complete blood cell count; C&S, culture and sensitivity; ECG, electrocardiogram; GFR, glomerular filtration rate; KPD, kidney paired donation; PSA, prostate-specific antigen; PT, prothrombin time; UA, urinalysis.

includes an assessment of patient history, including medical, surgical, family, and social history. There is no upper limit for donor age, but caution is advised in donors who are quite young (younger than 25 years). Particular attention to family history of diabetes, hypertension, and renal disease is critical for younger donors because they will have more years after donation to develop such diseases themselves. Potential donors should be in excellent health with no evidence of active malignancy or infection. In recent years, some transplant centers have accepted donors who have hypertension that is well controlled with a single antihypertensive medication (Karpinski et al, 2006). Ideally, living donors should have a body mass index (BMI) that is less than 30, but some transplant centers do accept individuals with BMI above 30. It is critical to counsel all donors to maintain a healthy weight as a preventive measure for developing diseases such as diabetes mellitus and/or hypertension that may subsequently contribute to renal damage. Testing should confirm normal cardiopulmonary function, absence of diabetes, and normal renal function.

Hyperfiltration injury has not been a significant problem for living renal donors. Endogenous creatinine clearance rapidly approaches 70% to 80% of the preoperative level, and this has been shown to be sustained for more than 10 years (Najarian et al, 1992; Ibrahim et al, 2009b). The development of late hypertension is nearly the same as for the general population, and the development of proteinuria is negligible (Steckler et al, 1990; Kasiske et al, 1995). Older donor age and increased BMI have been associated with the development of hypertension and GFR under 60 mL/min/1.73 m² (Ibrahim et al, 2009b). The mortality of kidney donation has been estimated to be 0.03% (Matas et al, 2003), the risk for a potentially life-threatening or permanently debilitating complication has been estimated to be 0.23%, and there are isolated reports of ESRD developing in renal donors (Rosenblatt et al, 2008; Tong et al, 2013; Schold et al, 2014). The short- and long-term risks of living-donor nephrectomy are generally considered to be low enough and the probability of successful graft outcome high enough to make the risks acceptable for fully informed donors.

The urologic evaluation begins with a thorough history that focuses on recurrent UTIs, nephrolithiasis, genitourinary malignancy, congenital issues such as vesicoureteral reflux, and hematuria. The renal anatomy is evaluated with CT angiography of the abdomen and pelvis and should include an excretory phase to evaluate the renal collecting system and ureters. Potential recipients with a history of urolithiasis should undergo a complete metabolic stone workup. Multiple stone episodes, or the presence of multiple stones at the time of the donor evaluation, are generally considered a contraindication to donation. Patients with a single, small stone can be considered for donation if their metabolic evaluation is normal.

Women of childbearing age should be informed that pregnancy outcomes after kidney donation were similar to those reported in the general population, but inferior to predonation pregnancy outcomes (Ibrahim et al, 2009a). It is recommended that pregnancy should be delayed for at least 2 months after donation to assess renal compensation before conception (Delmonico, 2005). Hydro-nephrosis during pregnancy is more common on the right side, but to date there are no reports to demonstrate more complications with left donor nephrectomy. We advise women to be closely monitored by an obstetrician during pregnancy after kidney donation.

Managing Incompatible Living Donor and Recipient Pairs

Approximately 35% of medically suitable donors are found to be incompatible with their intended recipient because of blood-type incompatibility, and 30% of the recipients have HLA antibodies as a result of prior blood transfusions, transplants, or pregnancy (Segev et al, 2005). Traditionally, to avoid rejection, incompatible patients in this situation were told not to proceed with living-donor transplantation, but rather to wait for a compatible deceased-donor organ. With over 100,000 patients on the deceased donor wait list, patients in many parts of the country must wait for nearly 10 or more years before they are transplanted. Approximately 4000

patients on the wait list will die per year. For these reasons, multiple strategies are now employed to facilitate living-donor renal transplantation for incompatible pairs.

ABO blood-type incompatible transplantation has been performed with acceptable graft and patient survival, but longer term results are not equivalent to blood-type compatible living-donor transplants (Montgomery et al, 2012). Protocols for such transplants vary widely across different programs but may include plasmapheresis, IV immunoglobulin (IVIG), rituximab, and/or splenectomy to bring anti-ABO titers to acceptable levels. In general, ABO-incompatible recipients also require more intensive immunosuppressive regimens.

Kidney transplantation with known HLA DSAs also may be performed despite a higher risk for antibody-mediated rejection. Depending on the strength of crossmatch positivity being caused by HLA antibodies, patients may require treatments such as IVIG and/or plasmapheresis before proceeding with transplantation. As with ABO-incompatible transplantation, protocols vary widely across different centers. Donor-specific antibodies that are considered weak may not cause a positive flow cytometric or cytotoxic crossmatch, and some centers choose to proceed with no pretransplant therapy. Patients who undergo renal transplantation with known DSA require periodic monitoring to ascertain the return of strong antibodies that were previously known, or de novo DSA, both of which put the patient at risk for antibody-mediated rejection.

KPD, which encompasses chains and exchanges, has emerged as a third modality to facilitate living-donor kidney transplantation for incompatible donor and recipient pairs. Incompatible pairs are placed into a pool of other incompatible donor and recipient pairs, and compatible matches are then found by matching algorithms built into software programs. Large multicenter databases of incompatible pairs maximize the chances of finding compatible matches for participants (e.g., Alliance for Paired Donation, 2009; National Kidney Registry, 2014; United Network for Organ Sharing, 2014a). Initially, KPD comprised simple, one-way swaps between two incompatible donor and recipient pairs (Fig. 47-3). Paired donation chains can be started by "Good Samaritan"

Figure 47-3. Kidney paired donation (KPD) simple two-way swap. An example of KPD between two ABO-incompatible donor and recipient pairs. KPD is employed in this situation as a simple swap that results in two blood-type compatible, living-donor transplants.

Figure 47-4. Kidney paired donation (KPD) chain. A nondirected donor is able to start a KPD “chain” that is theoretically never ending. In the chain depicted, both blood-type incompatibility and incompatibility because of a positive crossmatch are overcome by KPD, thereby allowing for multiple living-donor transplants to occur. Donors and recipients are often at different transplant centers, and transcontinental shipping of living-donor kidneys via commercial airlines has become widely accepted with excellent results.

donations, also known as nondirected donors (NDDs), who are remarkable individuals who seek to donate a kidney to a complete stranger in need. When a KPD chain is started by an NDD the number of living-donor transplants that result are theoretically unlimited; chains are often ended by offering a living-donor kidney to an individual on the deceased-donor waiting list (Fig. 47-4). The most successful KPD programs involve transplant centers all across the United States, and the transcontinental shipping of living-donor kidneys via commercial airline has greatly facilitated more KPD transplants without compromising results (Melcher et al, 2012). UNOS has recognized the importance of KPD as a method for increasing the number of living-donor transplants that can be performed and is currently evaluating the best way to maximize the potential of paired exchange (Organ Procurement and Transplantation Network, 2013).

If compatible living-donor pairs participate in a kidney exchange program, a recipient might benefit from a younger donor or a better histocompatibility match. Innovative computer software and the ability to perform virtual crossmatch testing continue to improve the efficiency of KPD.

Living Kidney Donor Operation

The laparoscopic donor nephrectomy (LDN) has become standard of care for the recovery of kidneys from living donors. The LDN has a low complication rate (6% minor, <2% major) and very low mortality rate of 0.03% (Harper et al, 2010; Segev et al, 2010). The

technique of LDN is nearly identical to that of a standard laparoscopic nephrectomy. Many centers have adopted a laparoscopic (Fig. 47-5A), hand-assisted laparoscopic (Fig. 47-5B), or robot-assisted technique. Open donor nephrectomy is rarely performed at this point but is typically accomplished through an extraperitoneal flank approach. Conversion to an open nephrectomy is not considered a complication of laparoscopic surgery, and donors should be counseled and consent received for this possibility before donation.

Special attention is paid to preserving adequate renal vessel and ureteral length for the recipient operation. Although most LDNs are left sided (because of the longer left renal vein), right-sided LDN is performed as well when indicated to preserve the “better” kidney for the donor. It is not necessary to administer IV heparin to the donor (Perry et al, 2002). The ureter is mobilized to the point at which it crosses the iliac vessels. It is unnecessary to include the gonadal vein with the ureter, and the gonadal artery should also be left intact for the donor when possible (Breda et al, 2006). The safest method for ligating the renal vessels is to employ a surgical stapling device with a vascular staple load. Stapling does not compromise vessel length for the recipient operation. Hem-o-lock clips are contraindicated in LDN because they have been associated with living-donor deaths when used to seal the aortic side of the donor renal artery. Once the kidney is removed, the renal arteries are immediately cannulated and the kidney is flushed with ice-cold heparinized (5000 U/L) lactated Ringer solution or an organ preservation fluid (if shipped).

Figure 47-5. Pure laparoscopic and hand-assisted laparoscopic left donor nephrectomy. **A,** Diagram showing the location of the incision and trocar placement for left laparoscopic donor nephrectomy. **B,** Hand-assisted left laparoscopic donor nephrectomy. For a laparoscopic single-site procedure all trocars are inserted via the perumbilical incision.

Figure 47-6. A to G, Methods of extending the right renal vein include modifications of the inferior vena cava and a free graft of donor external iliac vein. The first two methods are valuable when the cephalad portion of the right renal vein has been compromised by the separation of the liver graft from the kidney grafts. Spiral gonadal vein graft extension of right renal vein in living renal transplantation. *J Urol* 1989;142:1525.)

KIDNEY TRANSPLANT OPERATION

Allograft Preparation

Meticulous preparation of the renal allograft is essential. The renal vessels and ureter should be identified. The adipose tissue surrounding the kidney parenchyma is then carefully dissected off the vessels. Branches that drain into the renal vein, such as the left adrenal vein, should be ligated. Small accessory renal veins may be ligated and divided to increase the length of the main renal vein. Caution is advised in ligating large, or even medium-size accessory veins, because venous congestion has been observed. A number of techniques have been described to extend the renal vein if necessary (Fig. 47-6). Arterial branches greater than 0.5 mm in diameter should be preserved if possible (Shapiro, 1997). Fatty tissue close to the renal hilum should be ligated, because this tissue

often contains lymphatic channels that may otherwise contribute to a postoperative lymphocele.

Recipient Operation

The recipient is placed supine on the operating table and appropriately padded, and general inhalational anesthesia is induced. Prophylactic IV antibiotics are given, and a central venous catheter is placed. A urethral catheter is placed and attached to a three-way tubing system that allows for bladder filling and drainage during the operation, which can be helpful during the ureteroneocystostomy (Fig. 47-7). The bladder irrigant is preferably a broad-spectrum antimicrobial solution such as bacitracin or neomycin-polymyxin B. The bladder should be rinsed with this solution before start of the operation. If bowel has been used for urinary reconstruction, all mucus should be completely irrigated. To ensure proper blood

Figure 47-7. Bladder irrigation setup. This tubing system is compatible with any urinary catheter. The bladder can be filled and emptied many times without having the perineum in the operative field.

pressure once the kidney transplant is reperfused, the central venous pressure should be maintained between 10 and 15 cm H₂O with IV crystalloid and colloid solutions to achieve a mean arterial pressure that is ideally greater than 80 mm Hg. In patients who do not achieve these pressures with IV fluids only, judicious use of a dopamine drip can be considered. The perioperative induction immunosuppression should be reviewed and communicated to the anesthesia team.

A variety of incisions can be used for the recipient operation, but adequate surgical exposure that allows for vascular control is paramount. It is desirable to place the kidney extraperitoneally with the vascular anastomosis to the iliac vessels. The extraperitoneal approach is advantageous in minimizing potential complications and postoperative ileus. A Gibson incision over the right or left iliac fossa offers excellent exposure of the iliac vessels and the urinary bladder. A midline incision can be used and may be particularly useful in cases in which the vascular target includes the aorta and inferior vena cava. On rare occasions the vascular targets also may include the splenic and/or portal systems.

When a Gibson incision is used, the peritoneum is retracted medially and the retroperitoneal space overlying the iliac vessels is developed using a combination of blunt dissection and electrocautery. The inferior epigastric vessels can usually be gently retracted, but they may be divided if surgical exposure is compromised. Similarly, the round ligament may be preserved in females. The spermatic cord is identified in men as it travels inferiorly exiting the peritoneum and is carefully preserved. A self-retaining retractor is placed, without compression of the femoral canal, and the iliac vessels are exposed using the electrocautery. Lymphatic tissue overlying the vessels should be ligated or sealed with electrocautery. Care is taken to avoid injury of the genitofemoral nerve that lies anterior to the psoas muscle just lateral to the external iliac artery. Before anastomosis the kidney can be wrapped with sterile saline ice in a laparotomy sponge to keep the graft cool until reperfusion.

Figure 47-8. Typical anatomy of a kidney transplant. The renal vein is anastomosed to the external iliac vein, usually medial to the external iliac artery. When the recipient has a tortuous iliac artery, the venous anastomosis is best performed lateral to the bowed external iliac artery. In the absence of significant recipient arteriosclerosis, the renal artery is commonly anastomosed to the external iliac artery with 5-0 or 6-0 monofilament, nonabsorbable sutures. If significant iliac arteriosclerosis is present or the vessels are short, the common iliac artery or aorta becomes the target vessel for renal artery anastomosis.

For the vascular anastomosis, the preferred target sites are the external iliac artery and vein. In a living-donor transplant in which the donor vessels are shorter, the common iliac artery is often used. The venous anastomosis is generally performed first to limit ischemia to the leg. The venous target is occluded using vascular clamps or Rummel tourniquets according to surgeon preference. A venotomy is performed with a curved-blade scalpel, and heparinized saline solution is injected directly into the venotomy site to clear any blood or clots. A running end-to-side anastomosis is then performed with nonabsorbable monofilament polypropylene suture. The arterial anastomosis is then performed in a similar fashion. Patients with ESRD, and those with long-standing diabetes, in particular, are commonly found to have significant arteriosclerosis, and great care should be taken to recognize and avoid intimal disruptions that may lead to arterial dissection. A 2.7- to 6-mm punch facilitates the recipient arteriotomy if a donor arterial patch is not available. Before reperfusion an IV bolus of furosemide and mannitol may be administered to facilitate diuresis and act as a free-radical scavenger. Once the vascular anastomoses have been completed, the occluding clamps are removed—venous followed by arterial—and the kidney reperfused. Hemostasis is achieved, and the kidney is rewarmed with copious amounts of warm sterile saline. The allograft is then positioned in the iliac fossa such that there is no kinking of the transplant vessels (Fig. 47-8).

Figure 47-9. Two examples of extravesicular ureteroneocystostomy. **A**, Lich-Gregoir. An anterolateral seromuscular incision is made down to the bulging bladder mucosa. The bladder is drained, the mucosa incised, and the ureter anastomosed to the bladder (as shown) with fine absorbable sutures. A distal anchoring stitch to hold the ureter to the bladder is used to prevent proximal migration in the tunnel (not shown). The seromuscular layer is then loosely closed over the ureter. **B**, Barry. Steps a through c are completed with the bladder full of an antibiotic solution. The anesthesiologist unclamps the catheter before mucosal incision, and steps d through g are completed with fine absorbable sutures. (A, From Konnak JW, Herwig KR, Finkbeiner A, et al. Extravesicular ureteroneocystostomy in 170 renal transplant patients. *J Urol* 1975;113:299–301; B, from Barry JM. Unstenated extravesicular ureteroneocystostomy in kidney transplantation. *J Urol* 1983;129:918–9.)

The preferred technique for restoring continuity of the urinary tract with the transplant ureter is to create an antirefluxing, extravesicular, stented ureteroneocystostomy (Lich et al, 1961; Gregoir, 1962). This technique is easily reproducible in both normal and small contracted bladders, requires less ureteral length, and is generally faster than intravesicular techniques. Effort to create an antirefluxing tunnel is important to help prevent reflux of infected urine into the allograft, which may cause transplant pyelonephritis. Other extravesicular techniques have been employed, including the Barry and single-stitch techniques. It is useful to be familiar with all of them, and they should be used according to surgeon preference (Gibbons et al, 1992; Veale et al, 2007) (Fig. 47-9). The ureter should be passed below the spermatic cord, cut to allow for a tension-free anastomosis, and the periureteral tissue preserved to maximize the distal blood supply. If the allograft ureter appears compromised, options include a psoas hitch, a Boari flap, or using the ipsilateral native ureter. A double-pigtail ureteral stent should

be used in the majority of cases, because this has been shown to significantly decrease urologic complication rates (Wilson et al, 2013). Additionally, a closed suction drain is placed such that it lies in the area of the ureteral anastomosis and the vascular anastomosis. Ureteral anastomosis into a urinary diversion also should be performed with a ureteral stent, and a urinary catheter should drain the diversion as it would the native bladder.

Although indwelling urinary catheters and ureteral stents can reduce urologic complication rates, prolonged use places transplant recipients at higher risk for UTIs that may predispose them to rejection episodes. For this reason, it is recommended that the urinary catheter, closed suction drain, and ureteral stent be removed as soon as possible. In patients with reasonable bladder capacity, the urinary catheter may be removed on postoperative day 3 and the closed suction drain removed later in the day if drain output remains low.

Kidneys from small pediatric donors can be transplanted en bloc, or if deemed large enough, as single kidneys. When the

kidneys are transplanted en bloc, the entire donor aorta and inferior vena cava is typically anastomosed end to side to the iliac vessels. Because of the small size and tenuous blood supply of the ureters in such small donors, urologic complications such as urine leaks and ureteral anastomotic strictures are more common (Hobart et al, 1998). Pediatric-size ureteral stents should be employed, and consideration should be given to implanting the ureters separately such that a complication does not automatically affect both of the small allografts. Dual adult donor kidneys from marginal donors are generally not transplanted en bloc and may be placed together in the same iliac fossa or in both iliac fossae (Gill et al, 2008).

Robotic-assisted kidney and pancreas transplants have been reported (Giulianotti et al, 2010; Abaza et al, 2014). The potential advantages include a smaller incision, less pain, and a more rapid recovery. As robotic technology and operator skills improve, these small benefits may justify the added complexity, operative time, and cost associated with the procedures.

POST-TRANSPLANT CARE

Anticoagulation

Uremia can inhibit platelet aggregation and promote a bleeding tendency. Patients with coronary artery disease, particularly those with coronary stents, may take aspirin and other antiplatelet agents. Liver disease and prolonged exposure to antibiotics can lead to clotting factor deficiency. Anticoagulants such as warfarin may be prescribed to prevent fistula thrombosis or in patients with atrial fibrillation.

If a vascular anastomosis is difficult because of atherosclerosis, friable intima, small vessels, or pediatric recipient, intraoperative anticoagulation with 500 to 2000 U of IV heparin is indicated.

Perioperative anticoagulation must be individualized to take all of these factors into consideration. If the graft does not function immediately, percutaneous biopsy may be needed. Therefore long-acting anticoagulants are generally initiated once kidney function has stabilized. Low-molecular-weight heparin is eliminated by the kidney and must be used cautiously in the setting of unpredictable metabolism to minimize bleeding complications. A very low dose of IV heparin (100 U/hr) is used in the immediate postoperative period when the risk for coagulation is increased. The dose can be increased if bleeding is minimal or transitioned to antiplatelet therapy.

Surgical Complications

The most common early complications of renal transplantation include infection, bleeding, vascular thrombosis, urinary leak, and lymphatic leak. It should be noted that the signs and symptoms of surgical complications are similar to those of graft dysfunction in this population of patients. It is therefore important to consider immunologic causes as well.

Postoperative bleeding is usually discovered by abnormal vital signs and decreasing hematocrit values. Coagulation parameters should be checked. A large hematoma may compress the transplant kidney, negatively affecting renal function (Fig. 47-10). Patients who require multiple transfusions over a short period should be taken back to the operating room to evacuate any hematoma and to evaluate for a source of the ongoing bleeding. Transplant renal artery thrombosis is usually associated with delayed graft function or a hypercoagulable state, and patients with a known propensity for thrombosis should be given anticoagulation therapy. Renal artery thrombosis generally occurs within 3 days of the transplant and is associated with sudden cessation of urine output. Doppler ultrasound reveals no blood flow to the graft, and such grafts are rarely salvaged. Transplant renal vein thrombosis is also associated with a hypercoagulable state, kinking or stenosis of the vein, acute rejection, and hypotension. Doppler ultrasound may reveal a clot in the vein and decreased blood flow to the graft. As with renal artery thrombosis, emergent thrombectomy and antithrombotics should be attempted, but is rarely successful.

Figure 47-10. Subcapsular hematoma. Bleeding under the capsule of the kidney forms a hematoma (white arrow) which compresses the renal parenchyma (green arrow) resulting in reversal of diastolic flow on Doppler ultrasound.

Urinary leaks usually occur at the ureterovesical anastomosis and are associated with ischemic necrosis of the distal transplant ureter. Leaks manifest in the early postoperative period with decreased urine output from the urinary catheter and increased output from the closed suction drain. A urine leak is confirmed if the drain fluid creatinine is more than twice the serum creatinine or by nuclear medicine renal scan. In the case that the leak occurs after the urethral catheter has been removed, it should be replaced immediately. Many anastomotic leaks will heal with the ureteral stent in place and catheter drainage. Leaks that do not heal with conservative measures may require placement of a percutaneous nephrostomy tube or open repair.

Lymphoceles can originate from the transplant kidney or the lymphatic channels that surround the iliac vessels. Many lymphoceles are small and inconsequential, but large lymphoceles may cause pain, become infected, or compress the allograft, leading to dysfunction. Typically, lymphoceles are well visualized on ultrasound and can be initially treated with image-guided aspiration. Lymphoceles that reaccumulate require insertion of a closed suction drain. Rarely, a recurrent lymphatic leak may require use of sclerosing agents or even creation of a peritoneal window to aid in reabsorption (Chin et al, 2003). The incidence of lymphoceles can be reduced by routine placement of a closed suction drain that is removed when the daily output is less than 50 mL.

Rejection

The main function of the immune system is to protect against infection. Fundamental properties of the host defense include the ability to discriminate between self and nonself antigens and the ability to amplify the response on repeat exposure to foreign antigens. Investigating the cellular and molecular mechanisms involved in rejection of transplanted tissue has made a significant contribution to our understanding of the immune system.

Tissue that is moved from one place to another on the same individual, known as an **autologous** graft, is accepted as long as the appropriate blood supply and microenvironment exist. Similarly, tissue from genetically identical individuals, **syngeneic**, is accepted, whereas tissue from genetically different members of the same species, **allogeneic**, is usually rejected within a few weeks. Tissue from a different species, **xenogeneic**, is typically rejected very quickly.

Kidney transplant rejection can be classified by temporal occurrence of graft loss. **Hyperacute** rejection occurs shortly after the reperfusion of kidney transplants. Recipient cytotoxic antibodies and complement react with donor vascular endothelial antigens, leading to a rapid activation of the coagulation cascade and graft

thrombosis. This type of “humoral” rejection is rarely seen clinically today because of sensitive crossmatch tests to detect DSA.

Acute rejection classically occurs approximately 5 days after an allogeneic organ transplant without immunosuppression. Current immunosuppression protocols have reduced the rate of biopsy-proved acute cellular rejection to 10% to 15% in the first year. The most common manifesting sign is an increasing serum creatinine and decreasing urine output. Symptoms may include pain, swelling over the graft, malaise, and fever; but these are rare. Urinalysis may show proteinuria, hematuria, or pyuria. Imaging studies may demonstrate decreased cortical blood flow and tubular function. However, none of these findings is specific, so needle biopsy of the kidney graft is the current standard diagnostic test. The criteria for histologic classification of renal rejection were standardized at a series of meetings in Banff (Solez, 2010). The typical findings in acute cellular rejection are mononuclear infiltration of tubules and vessels. The deposition of complement fragments (C4d) in peritubular capillaries is now recognized as diagnostic of rejection frequently associated with donor-specific antibodies.

Chronic rejection is characterized by a gradual deterioration of kidney function. The histologic features of interstitial fibrosis, arteriolar sclerosis, and tubular atrophy rarely improve with augmented immunosuppression, and are in some cases the result of drug toxicity.

Immunosuppression Protocols for Kidney Transplantation

The success of organ transplantation requires a modulation of the immune response to nonself antigens expressed by the graft. The induction of donor-specific immune tolerance is the holy grail of transplantation. Tolerance would allow the immune system to accept donor organs, without compromising the normal response to infectious and malignant antigens. The fact that tolerance has been achieved in many animal studies but rarely in humans underscores the difficulty in moving this goal from the animal model to actual patients (Sykes, 2009). In successful hematopoietic cell transplantation, a balance between the host versus graft and graft versus host response allows cells from the donor and recipient to coexist. This symbiosis between donor and recipient usually requires matching of the MHC antigens, but this chimerism was recognized to also occur in some patients with poor matching and long-term function of solid-organ transplants (Starzl, 2004). Advances in immunosuppressive drugs have improved early graft survival rates, but these improvements have had little impact on late graft loss, largely because of chronic rejection. The induction of donor-specific immune tolerance would avoid these complications while also preventing chronic rejection.

Antibodies produced by B lymphocytes can recognize foreign antigens directly and are a principal component of the humoral immune response. The MHC plays an important role in the recognition of foreign proteins by the cellular immune response (Fig. 47-11). The class I antigens present peptide from endogenous proteins to CD8+ lymphocytes. Class II molecules present peptides from exogenous proteins to CD4+ lymphocytes.

The molecular mechanisms that are involved in the activation and proliferation of lymphocytes are the principal targets for blockade by pharmacologic immunosuppression. Three signals have been identified in T lymphocytes. Signal 1 is interaction between the MHC bound to antigenic peptide on an antigen-presenting cell (APC) with a specific T-cell receptor. Signal 2 is antigen-independent costimulatory interaction between molecules on the APC and T cell that lead to intracellular pathways, which stimulates interleukin-2 (IL-2) and other cytokines, as well as cytokine receptor expression. Signal 3 is stimulation of the IL-2 receptor, which leads to activation of the mammalian target of rapamycin (mTOR), which triggers cell proliferation.

Immunosuppression Protocols

Immunosuppressive protocols in kidney transplantation continue to evolve as our understanding of the biology of the immune response expands and pharmacologic agents to block the response

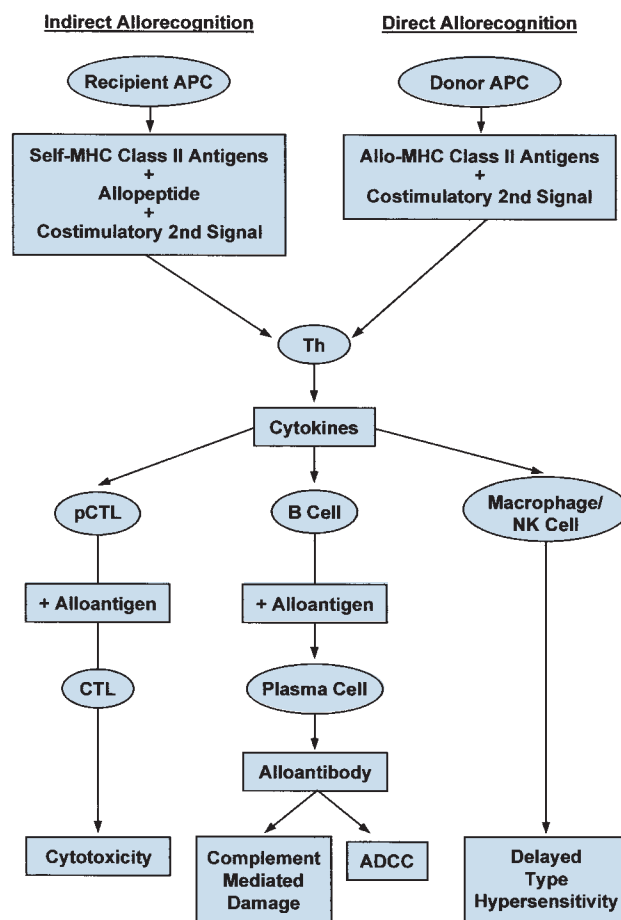

Figure 47-11. Cellular interactions in renal transplant rejection. CD4+ helper T cells (Th) are activated by antigen-presenting cells (APCs) that express incompatible major histocompatibility complex (MHC) class II antigens and provide a costimulatory second signal. The Th cells produce lymphokines that promote proliferation of B cells, maturation of CD8+ cytotoxic T lymphocytes (CTLs), activation of macrophages and natural killer (NK) cells, and induction of MHC class II antigens on renal cells. ADCC, antibody-dependent cell-mediated cytotoxicity; pCTL, precursor cytotoxic T cell.

are discovered. Antibiotics, including antifungal and antiviral drugs, also have permitted more intensive immunosuppression. Nearly all immunosuppression protocols were tested in animal models of solid-organ transplantation and then tested in humans. Some of the protocols have been developed through carefully designed clinical trials, but many have been introduced in off-label application by pioneering physicians and patients. In the 1950s the first protocols included *total-body irradiation* and *corticosteroids*. Shortly after the first successful identical twin transplant, *azathioprine* permitted graft survival with some living related donors. Most experimental models achieved superior outcomes if the T-lymphocyte population could be reduced and allowed to slowly recover. The administration of heterologous polyclonal serum from animals exposed to human immune tissue (*antithymocyte globulin*) and (*antilymphocyte globulin*) led to the concept of induction immunosuppression. It was also recognized that high doses of corticosteroids and lymphocyte depletion could reverse acute cellular rejection. Unfortunately, the 1-year graft survival was approximately 50%, with up to 20% mortality from infectious complications in this era.

In the early 1980s, *cyclosporine*, a calcineurin inhibitor, was introduced and maintenance immunosuppression in combination with azathioprine and prednisolone (triple therapy) improved 1-year graft survival rates to greater than 80%, including deceased and living-donor kidneys. The first monoclonal antibody in clinical medicine, *OKT3-antimurine CD3*, was approved in 1985 for the

treatment of steroid-resistant rejection. The success of solid-organ transplantation and the side effects of these drugs stimulated the pharmaceutical industry to develop more selective agents to target the transplant-specific immune response. Immunosuppression protocols are based on the risk for rejection (including donor and recipient factors), minimization of long-term side effects, and cost. The mechanism of action and toxicity of immunosuppressants are listed in Tables 47-3 and 47-4. Currently, the most common

protocols include a form of IV induction with antithymocyte globulin or *basiliximab*, and maintenance with *tacrolimus*, *mycophenolate*, and low-dose steroid (United States Renal Data System, 2013). Using these agents, biopsy-proved graft rejection rates are approximately 10% in the first year and mortality rates continue to improve, but approximately 40% of adult recipients become diabetic. Many of these drugs require continued monitoring of blood levels because metabolism can be affected by drug interactions (Box 47-3).

TABLE 47-3 Mechanisms of Action of Immunosuppressants

IMMUNOSUPPRESSANT	MECHANISM OF ACTION	INTERFERES WITH
Glucocorticoids	Reduce transcription of cytokine genes	Intercellular signaling
Azathioprine	Inhibits purine synthesis	Lymphocyte proliferation
Mycophenolate mofetil	Inhibits purine synthesis	Lymphocyte proliferation
Sirolimus	Inhibits cell cycle progression	Lymphocyte proliferation
Everolimus	Inhibits cell cycle progression	Lymphocyte proliferation
Tacrolimus	Inhibits calcineurin and IL-2 production	Intracellular signaling
Cyclosporine	Inhibits calcineurin and IL-2 production	Intracellular signaling
Rabbit antithymocyte globulin	Depletes T lymphocytes	Antigen recognition
Alemtuzumab (off label)	Depletes T and B lymphocytes	Antigen recognition and antibody production
Rituximab (off label)	Depletes B lymphocytes	Antibody production
Bortezomib (off label)	Proteasome inhibitor	Antibody production
Basiliximab	Blocks IL-2 receptor	Intercellular signaling
Belatacept	Costimulation blockade	Lymphocyte activation
Eculizumab (off label)	Complement inhibitor	Antibody-mediated rejection

IL-2, interleukin-2.

TABLE 47-6 Postoperative Infection and Peptic Ulcer Prophylaxis

PROBLEM	COMMONLY USED DRUG PROPHYLAXIS	ALTERNATE(S)
Urinary tract infection	Trimethoprim-sulfamethoxazole × 3 mo	Nitrofurantoin
<i>Pneumocystis</i> pneumonia	Trimethoprim-sulfamethoxazole × 3 mo	Pentamidine inhalant
Oral candidiasis	Nystatin suspension × 1–3 mo	Clotrimazole lozenges
Vaginal candidiasis	Clotrimazole vaginal inserts as needed	Nystatin inserts
Herpes simplex virus	Acyclovir × 3 mo if valacyclovir is not indicated	Ganciclovir, valacyclovir, famciclovir
Primary CMV disease	Valacyclovir	Ganciclovir
Recurrent CMV disease	Valacyclovir × 3 mo or during rejection therapy	Ganciclovir
Peptic ulcer disease	H ₂ -Receptor antagonist + antacid if symptomatic	

CMV, cytomegalovirus.

The development of new drugs in transplantation continues to focus on reducing nephrotoxicity, diabetes, and the gradual loss of renal function as a result of fibrosis. Despite the absence of cellular rejection, many patients will develop antibodies to antigens on the allograft, which is recognized as a significant risk factor for chronic transplant rejection. Many young patients will require more than one transplant procedure when their first transplant ultimately fails. New methods of monitoring the transplant immune response, preventing DSA, and treatments for humoral rejection are being investigated.

Infection

The timing of an infection after transplantation is critical to the appropriate diagnosis and management. Within the *first month* the organisms tend to be those causing infections at an institution in other patients with major urologic operations. The most common infections are related to technical complications of surgery and invasive medical devices and most commonly involve the genitourinary tract. The medical conditions of the patient, such as diabetes, malnutrition, obesity, abnormal urinary tract, and previous infections, increase the risk. Careful preparation of the donor graft, minimal blood loss, short ischemia time, mobilization of the patient, and prompt removal of catheters and drains reduces the risks for infection. One exception is a donor-derived infection of the graft or preservation solution. All infections should be treated with empirical antibiotics and adjusted based on the sensitivity of cultured organisms.

During months 1 to 6 after surgery, infections that are controlled by the cellular immune system are more prevalent. These opportunistic infections include fungi such as *Candida*, *Pneumocystis*, *Aspergillus*, and *Cryptococcus*; bacteria, including *Listeria monocytogenes*, *Nocardia*, and *Toxoplasmosis*; and viruses such as CMV, EBV, polyomavirus, hepatitis virus, and herpesviruses. The incidence of these infections is influenced by the recipient and donor history of preoperative exposure and augmented immunosuppression (Table 47-5).

Prophylactic treatment has significantly reduced the morbidity of immunosuppression (Table 47-6).

The infections that occur more than 6 months after transplant are influenced by graft function, risk for rejection, and previous infections. UTIs account for more than 15% of hospital readmissions in the first 2 years after kidney transplantation. Therapy should be based on a complete urologic physical examination and urine culture and sensitivity results. Recurrent UTIs should be evaluated for anatomic risk factors such as fistulas, incontinence, retention, reflux, and foreign bodies. Some patients with minimal pretransplant urine output need to be encouraged to increase fluid intake and void frequently. A voiding diary and assessment of postvoid residual facilitates patient education. If infections are infrequent, antibiotics should be provided to be initiated by the patient when symptoms occur. Some patients may benefit from continuous antibiotic suppression, but the risk for antimicrobial resistance and side effects should be minimized. Transplant vesicoureteral reflux with recurrent pyelonephritis may require ureteroneocystostomy.

Most UTIs do not improve with a reduction in immunosuppression. However, some viral infections such as adenovirus, which may manifest with hemorrhagic cystitis, and polyomavirus are exceptions. Adenovirus infection is usually self-limited and resolves with forced hydration. BK polyoma viral nephropathy can be detected by urine cytology, but is more commonly detected by polymerase chain reaction analysis of blood or urine samples. Treatment consists of reduction of immunosuppression and close monitoring of renal function.

Allograft Nephrectomy

Indications for removal of a failed kidney transplant are based mainly on signs and symptoms that happen as a result of immunosuppression withdrawal, including tenderness, graft enlargement, gross hematuria, and generalized flulike symptoms such as fever and malaise. If a patient is likely to be a candidate for

retransplantation, continued low-level maintenance immunosuppression may avoid the necessity of the allograft nephrectomy and reduce the production of HLA antibodies. Kidneys that fail within the first year of transplantation generally require removal. Those that fail as a result of chronic rejection are less likely to require removal and may be left in situ. Symptomatic patients may be treated with high-dose steroids to see if their symptoms resolve, obviating the need for allograft removal.

Allograft nephrectomy can be technically challenging, and referral to a surgeon who has experience with such procedures is advised. Within the first 6 weeks, removal of all transplanted tissue is generally a straightforward procedure. Symptomatic chronically rejected kidney transplants are generally removed in a subcapsular fashion because the capsule is likely to be adherent to the surrounding structures. The procedure carries the risk for significant perioperative morbidity, including acute hemorrhage, lymphatic leak, bowel injury, and abscess formation. The iliac vessels in the area of the allograft may become secondarily infected, leading to sepsis and/or vessel rupture.

Post-transplant Malignancy

Chronic immunosuppression increases the risk for malignancy. Skin cancer is the most common after solid-organ transplant. Malignancies associated with viral infection, including Kaposi sarcoma (human herpesvirus 8), non-Hodgkin lymphoma (EBV), and vulvar (human papillomavirus) and hepatocellular (HCV) carcinoma have a standardized incidence ratio (SIR) of greater than 5 compared to that of the general population. The incidence of kidney (SIR 4.7), bladder, and penile cancers are also increased, whereas the incidence of breast cancer was significantly decreased (SIR 0.85).

Surprisingly, the risk for prostate cancer is actually decreased in transplant recipients (SIR 0.92) (Engels et al, 2011). Therefore transplantation has little bearing on prostate cancer and the best treatment should be determined by grade, stage, estimated longevity, and patient preference. Given the increased mortality of many patients with ESRD, the risks and benefits of PSA screening should be discussed. If the native kidneys have acquired renal cysts as a result of prolonged dialysis, they should be monitored with annual renal ultrasound (Moudouni et al, 2006). Native nephrectomy is indicated for kidney transplant recipients with solid renal masses.

The interaction of urine with bowel segments may increase the risk for malignancy with immunosuppression. A history of enterocystoplasty or ureterosigmoidostomy should initiate a cancer surveillance program. The first-line adjuvant for superficial transitional cell carcinoma should be mitomycin, because thiopeta may have additive myelosuppressive effects. Bacillus Calmette-Guérin, a live attenuated bacterium, has been used in transplant recipients but may have a greater risk for systemic infection (Sun and Singh, 2010). A biopsy sample should be obtained of tumors within the kidney transplant. Lymphoma may respond to reduction of immunosuppression and has been described as post-transplant lymphoproliferative disorder. Partial nephrectomy has been curative in some donor-derived tumors.

Pregnancy and Childbearing

After successful kidney transplantation, levels of follicle-stimulating hormone, luteinizing hormone, and testosterone usually become normal and spermatogenesis improves (Akbari et al, 2003; Kheradmand and Javadneia, 2003). **Among male recipients who have fathered children, there has been no increase in congenital abnormalities in the offspring.** It is recommended, however, that impregnation be delayed for at least 1 year after transplantation (Armenti et al, 1998).

Successful renal transplantation usually restores fertility in premenopausal women. In a report based on thousands of pregnancies in renal transplant recipients, Davison and Milne (1997) reported the following: 94% of the conceptions that continued beyond the first trimester ended successfully; 50% of the deliveries were

TABLE 47-7 Pregnancy Safety and Immunosuppressants

B, no fetal risk in animals, no controlled studies; C, fetal risk cannot be ruled out; D, evidence of fetal risk.

Data from Physician's Desk Reference. 63rd ed. Montvale (NJ): Thomson PDR; 2009. p. 439, 625, 762, 1226, 2313, 2389, 2625, 3264; and U.S. Food and Drug Administration. <www.fda.gov> [accessed 03.09.09].

preterm; 30% of the women developed hypertension, preeclampsia, or both; intrauterine growth restriction occurred in approximately 20%; and rejection crises occurred in 10%. **There were no frequent or predominant abnormalities in the children, the transplanted kidney rarely caused dystocia, and the transplanted kidney was not injured during vaginal delivery.** An observational study of 16,195 female kidney transplant recipients documented a markedly lower pregnancy rate and higher fetal loss rate than reported in the general U.S. population during the same time (Gill et al, 2009). Pregnancy safety information for immunosuppressive drugs is listed in Table 47-7. Guidelines for successful pregnancy are good general health for 2 years after transplantation, minimal proteinuria, no hypertension, no rejection, no urinary tract obstruction, nearly normal renal function, and low doses of maintenance immunosuppressants.

AUTOTRANSPLANTATION

Renal autotransplantation was first described for the treatment of proximal ureteral injury (Hardy et al, 1967). The advantage of this technique over reconstruction with bowel includes the possibility of creating an antireflux anastomosis without mucous drainage and fewer bowel complications. However, it is a more complex operation with a greater risk for bleeding, vascular complication, and ureteral ischemia. Previously the technique was used for complex partial nephrectomy operations or extensive vascular reconstruction, but these operations now can be done either robotically or endoscopically in most cases. If a renal vascular injury is diagnosed, it may be possible to salvage the kidney if less than 90 minutes of warm ischemia have accrued and the patient is hemodynamically stable. The kidney and ureter should be removed and immediately placed in ice cold saline. The arteries should be flushed with heparinized saline. Occluded arteries may respond to thrombolytic therapy with urokinase, streptokinase, or tissue plasminogen activator (Nakayama et al, 2006). One of the advantages of this technique is complete denervation of the kidney. This has been useful as a last resort when other forms of pain management have failed. Relocation of the kidney into the pelvis with anastomosis of the renal pelvis to the bladder has been described for patients who are severe recurrent stone formers; autotransplantation in such cases promotes stone passage and allows for easy inspection with a flexible cystoscope (Flechner et al, 2011).

KEY POINTS

- The incidence of ESRD is greater than any urologic malignancy except prostate cancer.
- More patients die annually of ESRD than of any urologic malignancy.
- The first long-term success with human kidney transplantation occurred in 1954.
- Medicare coinsurance has been one of the most significant advances for the treatment of patients with ESRD.
- Evaluation of ESRD patients for renal transplantation is important to prevent wastage of kidney grafts because of transplantation into unsuitable recipients.
- New options are available to allow transplantation with ABO incompatibility and positive crossmatches between donors and recipients.
- Laparoscopic donor nephrectomy has reduced disincentives for living renal donors.
- Urologists must be aware of the urologic problems that may prevent or impair renal transplant technical success.
- Urologists must be aware of the potential genitourinary problems of transplant recipients.

Molecular Mechanisms of Tubulointerstitial Fibrosis

Clinical Impact of Renal Obstruction

Treatment of Renal Obstruction

Urinary tract obstruction is a major clinical problem that affects both children and adults and can result in permanent renal damage. The degree of injury to the kidney and the effect on overall renal function depends on the severity of the obstruction (partial or complete, unilateral or bilateral), the chronicity of the obstruction (acute vs. chronic), the baseline condition of the kidneys, and the presence of other mitigating factors such as urinary tract infection (UTI). The cause of urinary tract obstruction can be congenital or acquired and benign or malignant, and a list of possible etiologic factors is provided in [Box 48-1](#).

The histologic derangements associated with obstruction are localized primarily to the interstitial compartment of the kidney and include massive tubular dilation, progressive interstitial fibrosis, and a loss in renal mass secondary to apoptotic cell death ([Misseri et al, 2004](#)). These changes and any resulting impact on renal function are collectively referred to as *obstructive nephropathy*. Although urinary tract obstruction often results in *hydronephrosis*, or dilation of the renal pelvis and/or calyces, hydronephrosis can be present in the absence of obstruction. The diagnosis of urinary tract obstruction therefore requires other clinical and radiographic findings, rather than the presence of hydronephrosis alone.

PREVALENCE

Obstructive uropathy accounts for approximately 10% of all cases of renal failure. In an autopsy series of 59,064 individuals ranging from neonates to geriatric subjects, the prevalence of hydronephrosis was originally estimated to be 3.1% ([Bell, 1950](#)). Hydronephrosis was found to be more prevalent in women between the ages of 20 and 60 years, which was attributed to pregnancy and the development of gynecologic malignancies. In contrast, hydronephrosis was more prevalent in men after age 60 because of the presence of prostatic disease.

In consecutive autopsy series of 3172 stillbirths, infants, and children performed over a 12-year period, urinary tract malformations were found in 78 (2.5%) cases. Hydronephrosis and/or hydro-ureter accounted for 35.9% of urinary tract abnormalities ([Tan et al, 1994](#)). A slightly higher autopsy incidence of hydronephrosis in children (2%) was reported by [Campbell \(1970\)](#). Among children, hydronephrosis appears to be somewhat more prevalent in boys and the majority of cases occur in subjects younger than 1 year.

DIAGNOSIS AND IMAGING

Clinical Presentation

The clinical presentation of urinary tract obstruction can be quite variable depending on the site, degree, and chronicity of the obstruction. Flank pain secondary to stretching of the collecting system is the most common symptom in patients with acute obstruction; is typically an unrelenting, excruciating pain that can radiate to the lower abdomen and testicles or labia on the affected side; and is often associated with nausea or vomiting. In contrast, chronic obstruction of the urinary tract is usually a relatively painless phenomenon and patients may be entirely asymptomatic. Obstruction of the bladder outlet is most often associated with voiding symptoms of frequency, urgency, hesitancy, nocturia, poor urinary stream, and the sensation of incomplete emptying. Anuria is a rare but dramatic and fairly specific presenting sign of urinary tract obstruction.

Obstructive uropathy always should be considered in patients with new-onset hypertension and in patients with renal failure without a history of renal disease, diabetes, or hypertension. In addition, urinary tract obstruction always should be investigated as a possible contributing factor in patients with recurrent UTIs. Because the clinical signs and symptoms of obstructive uropathy are so variable, the diagnosis depends on prompt and appropriate imaging.

Laboratory Studies

The initial workup of a patient suspected of having urinary tract obstruction should begin with a urinalysis and microscopic analysis. An assessment of renal function and measurement of serum electrolytes should be performed, and in the patient with acute renal failure, an assessment of urinary diagnostic indices including the fractional excretion of sodium (FE_{Na}) should be performed.

Urinalysis

The urinalysis and microscopic analysis is necessary in the complete evaluation of a patient suspected of having urinary tract obstruction and/or renal failure. The urinalysis can provide an estimation of osmolality, evidence of UTI, insight into stone formation based

Fractional Excretion of Sodium

The FE_{Na} test often is used to differentiate among the three types of acute renal injury: prerenal, intrinsic, and postrenal.

$$FE_{Na} = (P_{Cr} \times U_{Na}) / (P_{Na} \times U_{Cr})$$

where P_{Cr} is defined as the serum creatinine level, U_{Na} is urine sodium level, P_{Na} is serum sodium level, and U_{Cr} is the urine creatinine level. An FE_{Na} less than 1% suggests a prerenal cause of acute renal failure (i.e., hypovolemia, congestive heart failure, renal artery stenosis, sepsis). An FE_{Na} greater than 1% will indicate intrinsic causes of acute renal failure (i.e., acute tubular necrosis, glomerulonephritis, acute interstitial nephritis), and an FE_{Na} greater than 4% indicates postrenal causes of acute renal failure (i.e., benign prostatic hyperplasia [BPH], bladder stones, bilateral ureteral obstruction [BUO]).

Assessment of Renal Function

Measurement of glomerular filtration rate (GFR) is considered the gold standard in identifying patients with renal insufficiency or renal failure. Normal GFR varies and generally decreases with age. The measurement of true GFR can be tedious and impractical; therefore a variety of tests are used to estimate GFR, with the most common being serum creatinine. Creatinine remains imprecise, however, because of variability with age, gender, race, and relationship with muscle mass. A number of formulas have been developed to estimate GFR using serum creatinine, age, and gender, including the Cockcroft-Gault formula (see below), the modification of diet in renal disease equation, and the newer Chronic Kidney Disease Epidemiology Collaboration equation.

$$\text{Estimated GFR (eGFR)} = (140 - \text{Age}) \times \text{Wt (kg)} \times (0.85 \text{ if female})$$

$$72 \times \text{Serum creatinine (in milligrams per deciliter)}$$

In general, a GFR greater than 90 mL/min/1.73 m² is considered normal, between 60 and 90 mL/min/1.73 m² is considered a mild

decline in renal function, between 30 and 60 mL/min/1.73 m² is a moderate decline in renal function, between 15 and 30 mL/min/1.73 m² is a severe decline in renal function, and less than 15 mL/min/1.73 m² is considered renal failure (Siddiqui and McDougal, 2011).

Diagnostic Imaging

Because the clinical presentation of the patient with urinary tract obstruction can be so variable, prompt and accurate diagnosis of obstruction depends on appropriate imaging. A review of the imaging modalities currently available and their advantages and limitations is presented in the following section.

Ultrasonography

Renal ultrasonography remains a first-line imaging modality in the evaluation of a patient suspected of having urinary tract obstruction because of its availability, low cost, and lack of ionizing radiation. It does not require the administration of iodinated contrast and can therefore safely be performed in patients with renal insufficiency or a contrast allergy. The renal ultrasound primarily provides anatomic information about the kidney, including renal size, cortical thickness, corticomedullary differentiation, and grade of collecting system dilation. Although the presence of hydronephrosis is suggestive of underlying obstruction, it is important to recognize that hydronephrosis is an anatomic finding, not a functional diagnosis, and that hydronephrosis alone does not indicate urinary tract obstruction. Significant hydronephrosis can be present in the absence of obstruction (e.g., in the patient with vesicoureteral reflux), and significant obstruction can be present in the absence of severe hydronephrosis, as is often the case very early in the course of acute renal obstruction. Parenchymal thinning and small renal size can be evidence of chronic renal obstruction, and bladder distention in association with hydronephrosis can be suggestive of bladder outlet obstruction. Standard renal sonography may appear normal in 50% of patients with acute urinary obstruction, and distinguishing obstructive from nonobstructive collecting system dilation can be difficult, especially when the obstructing agent is not visualized (Platt et al, 1989; Mostbeck et al, 2001).

The introduction of duplex Doppler sonography was subsequently suggested as a means to improve the ability of ultrasonography to diagnose renal obstruction in patients. In the early 1990s, changes in intrarenal arterial waveforms were shown to be associated with urinary obstruction, and the resistive index (RI) (defined as the peak systolic velocity–end diastolic velocity/peak systolic velocity) was advanced as a technique to improve detection of urinary obstruction during ultrasonography. It has been shown that after a short period of prostaglandin-mediated vasodilation, renal blood flow decreases and renal vascular resistance increases in response to obstruction. In general, an RI of 0.70 is considered to be the upper limits of normal in adults (Tublin et al, 2003), although important exceptions to this value have been reported. It is common for the mean RI to exceed 0.70 in children in the first year of life, and it can exceed 0.70 for at least the first 4 years. The RI also can exceed 0.70 in elderly patients without renal insufficiency. Initial clinical studies evaluating the RI threshold of 0.70 in the diagnosis of obstruction were encouraging, with a 92% sensitivity and 88% specificity. The diagnosis of obstruction increased further when the difference in RI (δ RI) between the affected kidney and contralateral kidney was found to be greater than 0.1 (Platt et al, 1989).

Although encouraging studies evaluating RI have been reported, subsequent clinical trials and animal studies investigating RI in the detection of renal obstruction have been discouraging. Chen and associates (1993) demonstrated that the RI is normal in most patients with partial or mild obstruction. Similarly, when discriminatory thresholds for obstruction (mean RI \geq 0.7, δ RI \geq 0.1) were used in the detection of patients with acute renal colic, the sensitivity and specificity of the Doppler examination was found to be only

44% and 82%, respectively (Tublin et al, 1994). It has subsequently been demonstrated that radiocontrast can induce vasoconstriction and increase RI during Doppler sonography (Hetzel et al, 2001) and that nonsteroidal anti-inflammatory drugs (NSAIDs) can significantly decrease the RI of acutely obstructed kidneys (Shokeir et al, 1999), both of which may have been factors confounding the results of clinical studies investigating RI in the diagnosis of renal obstruction. Despite these observations, however, skepticism over the utility of RI to detect renal obstruction has increased, and with widespread acceptance of noncontrast computed tomography (CT) scanning as the gold standard in the detection of renal calculi, the routine use of RI analysis in the evaluation of possible renal obstruction has declined.

Color Doppler ultrasonography has been shown to reliably identify ureteric jet dynamics in the bladder, and this has evolved as another diagnostic tool to distinguish obstructive from non-obstructive hydronephrosis. Burge and colleagues (1991) demonstrated that there was a significant decrease in the frequency of ureteral jets in patients with obstructing ureteral stones compared to the normal ureter. More recently, Jandaghi and associates (2013) demonstrated that there is a significant decrease in the frequency, duration, and peak velocity of urine jets emanating from the obstructed ureterovesical junction when compared to the contralateral side, and differences of 1.5 jets/min, 2.5 seconds, and 19.5 cm/sec in ureteral jet frequency, duration, and peak velocity, respectively, were proposed as cutoff points between obstructed and normal ureters. de Bessa and colleagues (2008) evaluated the frequency of urine jets in children who had obstructive versus nonobstructive hydronephrosis and demonstrated that a relative jet frequency (RJF = jet frequency of the hydronephrotic side divided by the sum of both ureteral jets over 5 minutes) of less than 25% had a sensitivity of 87% and a specificity of 96% in detecting obstruction. Although the analysis of ureteral jets is easily applied during routine ultrasonography and may offer some valuable insight into the presence of obstruction, it does require good hydration of the patient and is limited by the requirement of a normal contralateral collecting system for comparison.

One of the most common causes of urinary tract obstruction is the presence of renal or ureteral calculi. Although ultrasonography does not have the sensitivity of CT in detecting stones, it avoids the cumulative radiation dose from CT and can reveal secondary effects of urolithiasis, including hydronephrosis, infection, or abscess formation. It also has the advantage of detecting radiolucent stones. Ultrasound may detect calculi as small as 0.5 mm under optimal conditions, and stones typically manifest on ultrasound as echogenic foci in the collecting system associated with acoustic shadowing. In a recent pooled analysis, however, ultrasound was demonstrated to have only a 45% sensitivity and 94% specificity in detecting ureteral stones and 45% sensitivity and 88% specificity in detecting renal calculi compared to non-contrast CT (Ray et al, 2010). It has also been shown that ultrasound overestimates renal stone size compared to CT, particularly for stones 5 mm or less. Direct visualization of stones can be difficult on ultrasound, because of the presence of overlying bowel gas and the relative depth of the ureter within the pelvis, and can be further complicated in obese patients with large amounts of intervening fat (Cheng et al, 2012). Because of these limitations, ultrasound is primarily used as a first-line investigative tool only in pediatric and pregnant patients, but it can be used for routine follow-up in all patients with urolithiasis.

Nuclear Renography

Nuclear medicine plays a critical role in the evaluation of the patient with possible urinary tract obstruction because it is the only imaging modality that can provide noninvasive information about dynamic renal function. The nuclear study of choice in the evaluation of the obstructed collecting system is diuretic renography, most commonly performed using the radiopharmaceutical technetium-99m–mercaptoacetyl triglycine (^{99m}Tc-MAG3). ^{99m}Tc-MAG3 is preferred for diuretic renography because it has high

extraction by the kidneys, rapid clearance, low radiation dose, and tubular secretion. Renal uptake is 55% compared with 20% uptake by ^{99m}Tc -diethylenetriaminepentaacetic acid (^{99m}Tc -DTPA), the other radiopharmaceutical used for diuretic renography, resulting in better cortical imaging for both qualitative and quantitative analysis (He and Fischman, 2008). As opposed to ^{99m}Tc -MAG3, which is actively secreted by the tubules, ^{99m}Tc -DTPA is removed almost exclusively by glomerular filtration and is therefore the agent most suited to measurement of GFR. Adequate imaging of the collecting system, however, is GFR-dependent with DTPA and is quite limited in patients with renal insufficiency and those younger than 6 months of age because of the immaturity of renal function.

The normal renogram curve has three distinct phases. The initial phase is characterized by rapid uptake of the radiopharmaceutical by the kidneys, reflecting renal perfusion. The second phase is characterized by a more gradual rise in uptake over time, usually peaking after 2 to 5 minutes, and it is during the second phase that renal function is primarily evaluated. Urinary obstruction can diminish the rate of uptake of the radiotracer during the second phase and can therefore alter the assessment of differential renal function. The third phase is the excretory phase and is characterized by a gradual decrease in renal counts over time. The third phase is often augmented by the administration of a diuretic (diuretic renogram) to induce high urine flow and prevent the false positive results that can be caused by urine stasis in a dilated collecting system. By convention, a kidney is considered unobstructed if the time for half of the tracer to leave the collecting system ($T_{1/2}$) is less than 10 minutes, is equivocal if the $T_{1/2}$ is 10 to 20 minutes, and is considered obstructed if the $T_{1/2}$ is greater than 20 minutes. False-positive results can be seen in the presence of dehydration because of the suboptimal response to a diuretic agent, poor renal function, high-grade reflux, and in the presence of massive collecting system dilation with urinary stasis (Goldfarb et al, 2006). Renal immaturity in neonates also may generate false-positive results (Karam et al, 2003).

To improve the accuracy of diuretic renography and limit false-positive results, patients should be well hydrated for the study. The well-tempered renogram was originally described for children in 1992 as a means to ensure a standardized level of hydration with the administration of intravenous (IV) fluids before and during the course of the study (Conway and Maizels, 1992). Bladder distention and elevated bladder pressures can limit the ability of the upper urinary tract to drain and may artificially prolong the excretory phase of the study. Routine catheter placement is therefore recommended for any patient who is unable to urinate voluntarily and also should be considered for any patient with significant reflux, bladder pathology (i.e., neurogenic bladder), or a low-lying pelvic kidney from which the signal might be obscured by bladder filling. Patient position during the study also appears to affect results, and urine flow may be slow and resemble obstruction when the patient is supine. It is therefore suggested that a later static image be obtained in any patients with prolonged $T_{1/2}$ after they have assumed an upright gravity-assisted posture (Wong et al, 2000).

Timing of diuretic administration is somewhat controversial, and multiple different protocols have been established. Traditionally, furosemide is injected 20 minutes after the radiopharmaceutical is administered (F+20), although the diuretic can be administered 15 minutes before tracer injection (F-15) or at the time of tracer injection (F+0). The advantages of the F+20 technique are that the modifications to the drainage curve caused by furosemide can be observed, and if adequate kidney washout has occurred during the basic renogram, one can potentially avoid the administration of furosemide (Piepsz, 2011). With earlier administration of furosemide (F-15, F+0), urine flow is increased dramatically throughout the entire study, and Turkolmez and colleagues (2004) found that these protocols allowed clarification of obstruction in cases of equivocal F+20 studies. The disadvantage of the F+0 protocol is that early furosemide injection can result in acceleration of renal transit and an underestimation of renal function on the side with a short transit time (Donoso et al, 2003). A recent study suggested

improved results when patients were placed in a seated position and furosemide was administered 10 minutes after the radiopharmaceutical (F+10) (Tartaglione et al, 2013). It is important to keep in mind that measurement of differential renal function and tracer washout will vary depending on the protocol and radiopharmaceutical used, and care should be taken when interpreting results if comparative studies have been performed using different protocols or radiopharmaceuticals.

Computed Tomography

Cross-sectional imaging provided by CT generates greater anatomic definition than ultrasonography, and because of its speed, safety, and accuracy, noncontrast helical CT (NHCT) has become the imaging modality of choice for patients suspected of having ureteral obstruction. In a landmark study, Smith and colleagues (1995) demonstrated the superiority of unenhanced helical CT in the evaluation of possible ureteral obstruction compared to excretory urography. Unenhanced helical CT gives information about obstructing and nonobstructing stones, and it can reveal signs associated with ureteral obstruction even after stone passage, including hydronephrosis, perinephric stranding, and the "tissue rim sign." These secondary signs have been reported to have a positive predictive value of greater than 90% for the presence of acute ureteral obstruction (Smith et al, 1996; Heneghan et al, 1997). CT has a reported sensitivity of 96% for stone detection with a specificity and positive predictive value of 100% (Worster et al, 2002) and can detect most radiolucent stones with the exception of protease inhibitor stones (i.e., indinavir sulfate) and mucoid matrix stones. In addition, NHCT has been demonstrated to diagnose a wide spectrum of significant and alternative diagnoses in 10% of patients being evaluated for renal colic (Katz et al, 2000).

Although the unenhanced helical CT is the modality of choice in the evaluation of patients with acute renal colic, it has a limited ability to evaluate chronic obstruction of the urinary tract and various causes of obstruction other than calculi. Over the past decade, multidetector CT urography (CTU) has emerged as the imaging modality of choice for a comprehensive evaluation of the urinary tract (Washburn et al, 2009). The traditional CTU technique involves three imaging phases using a single IV bolus injection of contrast. An unenhanced phase is initially performed, followed by a nephrogenic phase obtained approximately 100 to 120 seconds after contrast injection, and an excretory phase is performed after a greater time delay to evaluate the urothelium. With the advent of improved software and high-resolution thin-slice CT scanning, three-dimensional reconstruction of the urinary tract can be performed and has been helpful in characterizing many obstructive lesions of the urinary tract. In addition to stones, calyceal diverticulum, crossing vessels causing ureteropelvic junction obstruction, duplication anomalies in nonfunctioning systems, ureteroceles, and ectopic ureteral insertions can all be visualized with good accuracy.

The primary concern regarding widespread use of CT is its high associated radiation exposure. The average mean effective dose for a single unenhanced CT has been reported to be 8.5 millisieverts (mSv) (Poletti et al, 2007) for a multidetector CT compared to 6.5 mSv for a single-detector CT and 1.5 mSv for an excretory urogram series (Katz et al, 2006). This dose can rapidly accumulate if there are multiple phases to the CT or the patient presents repeatedly. It has been estimated that the risk for fatal cancer is 0.05%, or 1 in 2000, for 10 mSv of ionizing radiation (Brenner et al, 2001). The risks are more concerning in children, because they are more sensitive to radiation-induced carcinogenesis and have a longer period for cancer to develop. A recent study demonstrated that children receiving a cumulative brain dose of 50 milligrays (mGy) or more from CT had a 2.8 times higher risk for developing brain cancer and those receiving a cumulative bone marrow dose of 30 mGy or more from CT had a 3.2 times greater risk for developing leukemia (Pearce et al, 2012; Miglioretti et al, 2013). Because of these risks, low-dose protocols have emerged with very little loss in diagnostic accuracy (Poletti et al, 2007). Stones

smaller than 3 mm, impaction at the ureterovesical junction, and patient obesity, however, have been shown to impair the diagnostic accuracy of low-dose techniques (Kennish et al, 2010).

Magnetic Resonance Urography

Magnetic resonance urography (MRU) is an imaging modality that integrates excellent anatomic information with functional data and avoids ionizing radiation. Because of its significant cost and restricted availability, it is not a first-line imaging modality in the evaluation of a urinary obstruction at this time, but because of its major advantages to conventional imaging, MRU has the potential to become the imaging study of choice for the evaluation of urinary tract abnormalities in the future. The MRU protocol begins with standard T1- and T2-weighted imaging through the abdomen and pelvis without contrast. Gadolinium-diethylenetriaminepentaacetate dimeglumine (Gd-DTPA) is then administered in conjunction with furosemide, and T1-weighted imaging is performed, allowing visualization of both the concentrating and excretory functions of the kidney. MRU measurements of differential renal function and contrast excretion have been shown to correlate well with DTPA nuclear scintigraphy (Perez-Brayfield et al, 2003), but MRU has the advantage of providing excellent anatomic visualization of even nonfunctioning renal moieties. The MRU measurement of contrast excretion is the renal transit time, which is defined as the time it takes for contrast to pass from the renal cortex to the proximal ureters, and is classified as normal if it is 4 minutes or less, equivocal if longer than 4 and less than 8 minutes, and obstructed if 8 minutes or longer (Jones et al, 2004). El-Nahas and colleagues (2007) reported that MRU has 100% sensitivity in diagnosing upper urinary tract obstruction, and MRU has been demonstrated to be valuable in diagnosing urinary tract abnormalities when traditional imaging is inconclusive (Payabvash et al, 2008). Unfortunately, MRU detection of renal and ureteral stones is poor in comparison to CT because stones appear as signal voids on T1- and T2-weighted images. MRU sensitivity for detecting stones has been reported to be 68.9% to 81% (Blandino et al, 2001; Shokeir et al, 2004), but accuracy is greatly improved with gadolinium-enhanced excretory MRU, with sensitivities approaching 90% to 100% (Cerwinka and Kirsch, 2010). The biggest risk of MRI is the development of nephrogenic systemic fibrosis, which was linked to gadolinium-based contrast agents in 2006 and appears to occur only in patients with severe renal impairment (Thomsen, 2006). The incidence of nephrogenic systemic fibrosis in patients with risk factors has been demonstrated to be 3%, and new recommendations now limit the use of gadolinium in patients with renal impairment (Cerwinka and Kirsch, 2010).

Excretory Urography

Excretory urography was previously considered the imaging modality of choice in the evaluation of patients suspected of having urolithiasis and/or urinary tract obstruction. Although it largely has been replaced with CTU, it does provide both anatomic and functional information and can be useful in certain clinical situations. Imaging during excretory urography depends on glomerular filtration and renal excretion of iodinated contrast medium; therefore the utility of excretory urography is limited in patients with renal insufficiency. The risk for contrast nephropathy also increases with worsening renal function. Excretory urography should not be performed in patients with a history of contrast allergy or those in whom radiation exposure is a concern (i.e., pregnancy).

A delay in contrast uptake and excretion by the kidney (delayed nephrogram) can be indicative of urinary tract obstruction, and the subsequent opacification of the collecting system with contrast can be helpful in identifying the level and potentially the source of obstruction. In addition, small renal size, parenchymal thinning, calyceal clubbing, and significant ureteral dilation and tortuosity can be signs of chronic urinary tract obstruction.

Whitaker Test

The Whitaker test, first described in 1973, is a urodynamic evaluation of the upper urinary tract that is helpful in differentiating an obstructed collecting system from an unobstructed hydronephrotic collecting system. Renal scintigraphy can give false-positive results in the face of massive collecting system dilation or poor renal function, because continued filling, rather than drainage, of the collecting system occurs in response to furosemide, leading to an apparent prolongation in the calculated washout time. The Whitaker test involves placement of a percutaneous needle in the collecting system of the kidney and the infusion of contrast at a rate of 10 mL/min. A urodynamic catheter is also placed in the bladder, and intravesical pressures are monitored and subtracted from measured intrapelvic pressures during the infusion. Intrapelvic pressures are noted at the time that contrast is first seen extending past the ureteropelvic junction and past the ureterovesical junction. Pressures less than 15 cm H₂O are considered normal, greater than 22 cm H₂O are indicative of obstruction, and between 15 and 22 cm H₂O are considered indeterminate. Although the reproducibility and clinical utility of the Whitaker test have been questioned (Djurhuus et al, 1985), the test recently has been shown to determine or contribute to therapeutic management in 84% of cases of suspected obstruction and to accurately predict both obstruction and nonobstruction in 77% of cases (Lupton and George, 2010). A study by Veenboer and de Jong in 2011 demonstrated a 100% negative predictive value in the ability of the Whitaker test to diagnose the absence of obstruction. Although the Whitaker test has limited applicability in clinical practice, it continues to have a valuable role in the evaluation of equivocal upper urinary tract obstruction, especially when noninvasive investigations are inconclusive.

Retrograde Pyelography

Retrograde pyelography refers to the injection of contrast into the upper collecting system through a cystoscopic approach. The technique accurately defines ureteral and upper collecting system anatomy and can determine the location of an obstructive lesion. It is most often used to define the anatomy of the collecting system when it has not been adequately defined by other imaging modalities or when a patient has risk factors for receiving iodinated contrast material. Because retrograde pyelography involves intubation of the ureter with a catheter, bacteria may be introduced into the upper urinary tract during the procedure. The technique is therefore associated with an increased risk for UTI/sepsis in the setting of obstruction if the collecting system is not subsequently drained.

Antegrade Pyelography

Antegrade pyelography is most often used when retrograde pyelography is not technically feasible or when other imaging studies do not adequately define the collecting system.

HEMODYNAMIC CHANGES WITH OBSTRUCTION

Glomerular Filtration and Renal Blood Flow

Many functional changes occur in the kidney associated with obstructive nephropathy that affect renal hemodynamics. To understand the relationship between changes in renal hemodynamics and the alterations in GFR that occur during and after obstruction, it is important to understand the factors that influence GFR. GFR is defined by the equation:

$$\text{GFR} = K_f(P_{GC} - P_T - \pi_{GC})$$

where K_f is a glomerular ultrafiltration coefficient related to the surface area and permeability of the capillary membrane. P_{GC} refers to glomerular capillary pressure, which is influenced by both renal plasma flow (RPF) and the resistance of the afferent and efferent

arterioles. The hydraulic pressure driving fluid into Bowman space is resisted by the hydraulic pressure of fluid within the renal tubules (P_T) and π_{GC} , which is the oncotic pressure of proteins in the glomerular capillary and efferent arteriole. In addition to tubular hydraulic pressure and the oncotic pressure of proteins in the capillary, glomerular capillary pressure is also influenced by RPF:

$$RPF = \frac{(\text{Aortic pressure} - \text{Renal venous pressure})}{\text{Renal vascular resistance}}$$

Renal Vascular Resistance

Renal vascular resistance is primarily mediated by changes in the resistance of the afferent and efferent arterioles; therefore constriction of the afferent arteriole will result in a decrease in P_{GC} and GFR, whereas constriction of the efferent arteriole will increase P_{GC} . Renal obstruction can transiently or permanently affect some or all of the determinants of GFR, depending on the length and degree of obstruction.

Unilateral Ureteral Obstruction

Differences exist in the hemodynamic changes that occur in response to unilateral ureteral obstruction (UUO) as compared to BUO. Animal experiments have demonstrated a triphasic pattern of renal blood flow (RBF) and ureteral pressure changes during UUO (Fig. 48-1). Initially, there is an increase in pressure within the renal tubules of the affected kidney secondary to obstruction and a subsequent decrease in GFR. The vasculature of the kidney attempts to compensate for the decreased GFR with an increase in RBF mediated by the release of vasodilators, such as prostaglandin E_2 (PGE_2) (Allen et al, 1978) and nitric oxide (NO) (Lanzone et al, 1995). This phase lasts 1 to 2 hours. During the

second phase, lasting 3 to 4 hours, ureteral pressure remains elevated but RBF begins to decline, and, in the final phase, both ureteral pressure and RBF flow progressively decline, resulting in a gradual loss in renal function (Vaughan et al, 1970; Moody et al, 1975). The late-phase decline in RBF and ureteral pressure appears to be mediated by an increase in afferent arteriolar resistance. In addition to impeding RBF, it has been shown that increased afferent arteriolar resistance causes a decrease in effective glomerular capillary pressure and a resulting decrease in renal tubular pressure (Arendshorst et al, 1974). During the late phase of obstruction, there is also a shift in RBF from the outer cortex to the juxtamedullary region of the kidney and large portions of the cortical vascular bed become unperfused or underperfused (Yarger and Griffith, 1974). Reduced GFR at this stage is therefore not only the result of a reduction in P_{GC} in individual glomeruli because of increased afferent arteriolar resistance but also occurs because of a global lack of perfusion of many glomeruli.

The mechanism of obstruction-induced increased afferent arteriolar resistance was initially thought to be due to upregulation of the renin-angiotensin system or increased thromboxane A_2 expression, but subsequent studies have not revealed a significant effect of these mediators on the renal hemodynamic response to obstruction (Vaughan et al, 2004). More recently, NO has been implicated in the late renal hemodynamic changes observed during UUO. NO is a vasodilator formed by the conversion of arginine to NO by nitric oxide synthase (NOS). NOS is present in the kidney, and the inducible form of NOS (iNOS) is upregulated in the kidney in response to obstruction (Miyajima et al, 2001b). A study by Felsen and associates in 2003 demonstrated that animals administered L-arginine demonstrated an increase in RBF and ureteral pressure in response to obstruction that was not observed in controls, suggesting that a lack of availability of substrate for NO production may be the mechanism of late-phase decreases in RBF and tubular pressure (Felsen et al, 2003).

Figure 48-1. Triphasic relationship between ipsilateral renal blood flow (RBF) and left ureteral pressure during 18 hours of left ureteral obstruction. The three phases are designated by Roman numerals and separated by vertical dashed lines. In phase I, RBF and ureteral pressure rise together. In phase II, the RBF begins to decline and ureteral pressure remains elevated. In phase III, the blood flow and ureteral pressure decline together. (From Moody TE, Vaughan ED Jr, Gillenwater JY. Relationship between RBF and ureteral pressure during 18 hours of total ureteral occlusion: implications for changing sites of increased renal resistance. *Invest Urol* 1975;13:246-51.)

Bilateral Ureteral Obstruction or Obstruction of a Solitary Kidney

BUO (or obstruction of a solitary kidney) is characterized by only a modest initial increase in RBF lasting about 90 minutes, followed by a decrease in bilateral RBF (Gulmi et al, 1995). Unlike UUO, in which the ureteral pressure is initially elevated but quickly decreases to preocclusion pressures by 24 hours, ureteral pressure remains elevated for at least 24 hours with BUO. This prolonged elevation in intratubular pressure contributes to the decrease in GFR observed with BUO. It has been shown, however, that the decrease in GFR and RBF is more pronounced in animals with UUO compared to BUO (Siegel et al, 1977). The mechanism of these hemodynamic differences appears to be related to the site of vasoconstriction in the glomerulus. During UUO, preglomerular vasodilation is followed by a more prolonged preglomerular vasoconstriction, and this increase in afferent arteriolar resistance causes a reduction in glomerular capillary pressure that in turn results in decreased intratubular pressure. In contrast, during BUO preglomerular vasodilation is followed by a prolonged postglomerular vasoconstriction. This increase in efferent arteriolar resistance results in increased P_{GC} and intratubular pressure despite a decrease in RBF. The positive effect of increased P_{GC} on GFR is offset by the persistent elevation in tubular pressure. As with UUO, it appears that NO has an important role in early vasodilation of the afferent arteriole (Reyes and Klahr, 1992). A number of other vasoactive mediators have been implicated in the hemodynamic changes observed during BUO. Inhibition of platelet-activating factor, a potent vasodilator, has been shown to significantly decrease GFR and effective RPF in animals with BUO (Reyes and Klahr, 1991), and inhibition of endothelin (a vasoconstrictor) in animals with BUO has been shown to attenuate the observed decreases in GFR and effective RPF (Reyes and Klahr, 1992). Although a number of different vasoactive mediators likely contribute to the hemodynamic response during BUO, atrial

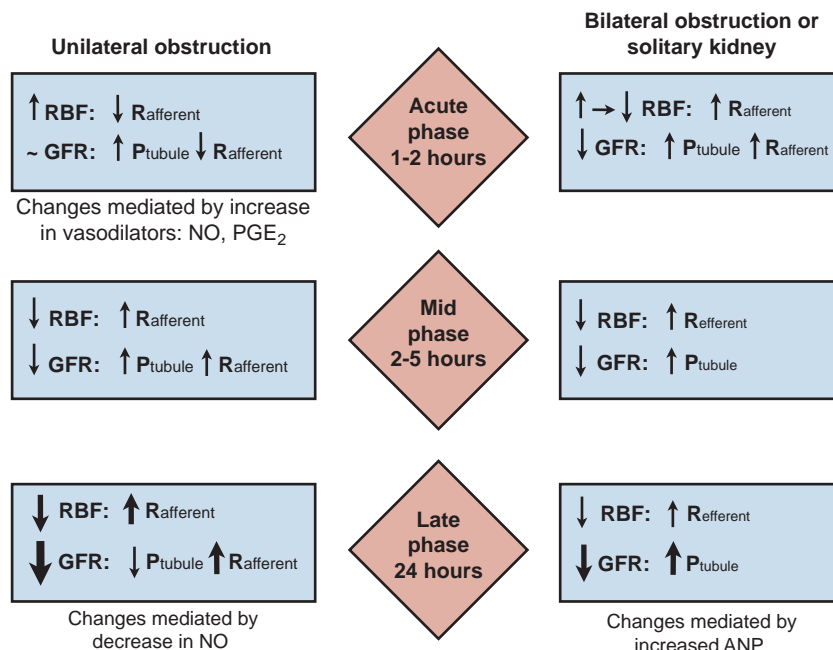

Figure 48-2. Summary of the functional changes during ureteral obstruction. ~, little change; ANP, atrial natriuretic peptide; GFR, glomerular filtration rate; NO, nitric oxide; PGE₂, prostaglandin E₂; P_{tubule}, tubular hydraulic pressure; RBF, renal blood flow; R_{afferent}, afferent arteriolar resistance; R_{efferent}, efferent arteriolar resistance.

natriuretic peptide (ANP) appears to have a unique role in BUO and may be largely responsible for the different hemodynamic response observed with BUO as compared to UUO. Because there is no second renal unit to compensate for the ureteral obstruction, intravascular volume increases in response to BUO and serves as a stimulus for secretion of ANP. ANP in turn increases afferent arteriolar dilation and efferent arteriolar vasoconstriction, leading to an increase in P_{GC} and intratubular pressure (Maack et al, 1996). It also decreases the sensitivity of tubuloglomerular feedback, inhibits release of renin, and increases the glomerular ultrafiltration coefficient K_f, which is related to the surface area and permeability of the capillary membrane. Indeed, high plasma levels of ANP have been demonstrated in animals with BUO as compared to control animals or those with UUO (Purkerson et al, 1989; Kim et al, 2001b), and it has been postulated that increased levels of ANP may exert a protective effect on GFR during BUO that is not seen with UUO.

The intrarenal distribution of blood flow is also quite different with BUO as compared to UUO. Animal studies have demonstrated that there is a shift of blood flow from the juxtamedullary region of the kidney to the outer cortex in response to BUO, which is the opposite of that seen with UUO (Jaenike, 1972; Solez et al, 1976). These alterations in the distribution of renal cortical blood flow also may contribute to the differences in GFR observed between BUO and UUO.

In summary, the hemodynamic changes observed with both UUO and BUO involve increases in renal vascular resistance and ureteral pressure. The timing and regulation of these changes, however, are different (Fig. 48-2). During UUO, early renal vasodilation is followed by prolonged preglomerular vasoconstriction that results in normalization of intratubular pressure. In contrast, during BUO there is little early vasodilation and the later postglomerular vasoconstriction is associated with increased intratubular pressures.

Partial Ureteral Obstruction

Although most models of urinary tract obstruction study complete obstruction over variable times, many clinical situations involve partial ureteral obstruction (PUO). The effects of PUO on renal

hemodynamics and GFR are variable, depending on the severity and the duration of obstruction. In general, PUO results in decreased RBF and GFR in the ipsilateral kidney (Wen et al, 1999; Wen, 2002). Chronic PUO has been reported to decrease RBF to 25% of normal (Stecker and Gillenwater, 1971), and a shift in renal cortical blood flow from the outer cortex to the inner cortex has been documented (Yarger et al, 1980). It appears that the degree of RBF decline depends on the severity of obstruction (Chevalier, 1984; Chevalier and Kaiser, 1984). Although PUO has not been studied as extensively as UUO, a similar array of vascular mediators have been implicated in the increased afferent arteriolar resistance that occurs in response to PUO, including prostaglandins (Ichikawa and Brenner, 1979) and the renin-angiotensin system (Beharrie et al, 2004). A major problem with studies involving partial obstruction is the ability to accurately reproduce the degree of obstruction in each animal. Thornhill and associates (2005) describe a method of ligating the ureter over a wire of calibrated diameter, which then can be removed to create a partial obstruction. The authors found that when the ureter was reduced by 70% to 75%, GFR was reduced by 80% after 28 days of partial UUO.

EGRESS OF URINE FROM THE KIDNEY

Although normal flow of urine from the kidney through the urinary tract is compromised with obstruction, urine may still egress from the kidney. A rupture of the calyceal fornix and subsequent extravasation of urine can occur during acute obstruction, typically in response to ureteral stones (Stenberg et al, 1988), although it also can be seen with congenital abnormalities such as posterior urethral valves. Extravasation of urine into the venous and lymphatic system also may occur in the setting of urinary obstruction. During chronic obstruction, fluid is thought to exit primarily into the renal venous system.

EFFECTS OF OBSTRUCTION ON TUBULAR FUNCTION

Obstruction of one or both kidneys can have profound effects on the concentrating ability of the kidney and on sodium, potassium,

and hydrogen excretion. The ability of the kidney to recover normal excretory function after relief of obstruction depends on the degree and severity of obstruction. Postobstructive diuresis often will accompany relief of BUO but is not typically observed with relief of UUO, secondary to the presence of a functional contralateral kidney that can maintain fluid balance. The eventual correction of abnormal renal tubular function depends on the degree and duration of obstruction.

Urinary Concentrating Ability

Normal urine concentrating ability depends on a hypertonic medullary interstitial gradient, which is established by active sodium transport out of the tubule and the countercurrent exchange mechanism. It also depends on the variable permeability of the tubules to water, mediated by aquaporin (AQP) water channels. Obstructive nephropathy can disrupt all or some of these mechanisms and lead to a defect in urine concentrating ability.

AQPs are protein channels that form pores in the membrane of renal tubular cells. AQPs selectively conduct water into and out of the cell and are essential for the urine concentrating ability of the kidney. Aquaporin 2 (AQP2) is exclusively expressed in the principal cells of the collecting tubule and collecting duct and is the predominant vasopressin-regulated water channel. Vasopressin is secreted into the bloodstream from the posterior pituitary gland in response to increased serum osmolality or a reduction in circulating volume. After vasopressin binds to cell surface receptors in the collecting tubule, cytoplasmic vesicles containing AQP2 channels fuse with the apical membrane of tubular cells to facilitate water movement out of the collecting duct and its subsequent reabsorption.

After 24 hours of BUO there is a marked reduction in AQP2 expression in the kidney (Frøkiaer et al, 1996; Stodkilde et al 2011), which results in an impaired ability of the kidney to reabsorb water once the obstruction has been relieved. It has been demonstrated that AQP2 expression remains 50% of normal levels 7 days after relief of obstruction. AQP1, 3, and 4 expression levels also have been shown to be downregulated in response to BUO (Li et al, 2001; Nielsen et al, 2007), and although AQP2 and AQP3 expression will normalize within 30 days of release of BUO, AQP1 remains downregulated and may contribute to the long-term polyuria and impaired concentrating ability of obstructive nephropathy. Downregulation of AQP channels is also observed in response to UUO, but the clinical manifestations are not as evident because the contralateral kidney is able to regulate fluid balance. A significant decrease in AQP2 levels is observed in the obstructed kidney (23% normal), and a moderate decrease in AQP2 levels is observed in the nonobstructed kidney (75% normal) after 24 hours of UUO (Frøkiaer et al, 1997), suggesting both local and systemic effects on AQP expression. Angiotensin has been implicated in obstruction-induced AQP2 downregulation, because blockade of the angiotensin I receptor has been shown to prevent the decreased expression of AQP2 (Jensen et al, 2006), and antioxidants, such as *N*-acetylcysteine, appear to upregulate AQP2 expression and protect against the urinary concentrating defect caused by obstructive injury (Shimizu et al, 2008).

Sodium Transport

A decrease in sodium transport in the nephron is observed after release of obstruction, and this salt wasting also contributes to the concentrating defect observed in response to obstruction. Previous studies have indicated that the major defects in renal tubular sodium reabsorption localize to the distal segments of the nephron (Li et al, 2003; Jensen et al 2006). A significant downregulation in major sodium transporters occurs within the nephron 24 hours after the onset of UUO and occurs in both the obstructed and unobstructed kidneys. Similarly, a significant downregulation in major sodium transporters occurs in response to BUO, and in both models of injury the downregulation in sodium transporters has

been shown to contribute to the observed natriuresis (Li et al, 2003; Jensen et al, 2006). The natriuresis following relief of BUO is typically greater than that after UUO because BUO causes retention of sodium, water, urea nitrogen, and increased production of ANP, all of which stimulate sodium wasting after relief of obstruction.

PGE₂ has an important role in tubular water and salt transport and the regulation of renal hemodynamics (Harris and Breyer, 2001). It has been demonstrated that PGE₂ inhibits NaCl reabsorption in the thick ascending limb of the loop of Henle and vasopressin-induced increases in water permeability in collecting ducts (Torikai and Kurokawa, 1983; Aarab et al, 1999). Cyclooxygenase (COX) is the rate-limiting enzyme in the synthesis of prostaglandin from arachidonic acid, and Norregaard and associates (2005) demonstrated that COX-2 and PGE₂ synthesis are upregulated in the kidney in response to 24 hours of BUO and that COX-2 inhibition prevents PGE₂ release and the observed downregulation in AQP2 and major sodium channel expression in response to obstruction.

Hydrogen Ion Transport and Urinary Acidification

Obstruction causes a deficit in urinary acidification that has been demonstrated in human subjects and animal models. The defect is characterized by the inability of the kidney to lower urinary pH maximally (<5.5) under the stimulus of systemic acidemia. Evidence suggests that the major acidification defect is in the distal nephron, most likely related to defective H⁺ secretion in the distal tubule and collecting duct and/or decreased bicarbonate reabsorption in the juxtamedullary nephron. Obstruction has been demonstrated to significantly decrease the expression of multiple acid-base transporters in the kidney, including the type 3 Na⁺/H⁺ exchanger, the electrogenic Na⁺/HCO₃⁻ cotransporter, the Na⁺-K⁺ (NH₄⁺)-2Cl⁻ cotransporter, and the electroneutral Na⁺/HCO₃⁻ cotransporter, in addition to decreasing the expression of H⁺-ATPase in the kidney (Wang et al, 2009). Valles and Manucha (2000) demonstrated that the decrease in H⁺-ATPase observed during UUO is mediated by an increase in iNOS, which in turn appears to be regulated by angiotensin II.

In the proximal tubule, glutamine uptake and ammonia generation are diminished after release of obstruction, resulting in a greater proportion of H⁺ that will be buffered as a titratable acid in combination with phosphate, creatinine, and other bases. The largest component of titratable acid is phosphate, and because phosphate excretion may be compromised in response to obstruction, the net result may be a lower urinary pH related to unbuffered protons in spite of a net decrease in total H⁺ secretion.

Other Cation Transport

Obstruction has an effect on other cation transport as well. In UUO, potassium secretion is decreased in proportion to the decrease in GFR after release of a 24-hour period of UUO (Harris and Yarger, 1975). This may be due to reduced delivery of sodium to the distal nephron and a low flow state, although other investigations also indicate an intrinsic defect in potassium secretion (Thirakomen et al, 1976). In contrast, potassium excretion increases in parallel with sodium excretion after relief of BUO, and it appears that proximal reabsorption of potassium remains unchanged whereas its secretion in the collecting duct is increased after relief of obstruction. This may be related to increased water and sodium delivery to the collecting duct and to the presence of high levels of ANP that can stimulate potassium secretion in the distal nephron (Sonnenberg and Wilson, 1976). Magnesium excretion is also markedly increased after release of either UUO or BUO. This most likely results from compromised transport in the thick limb of Henle. The effects on phosphate reabsorption after the release of obstruction vary depending on whether it was bilateral or unilateral. When BUO is released, accumulated phosphate is rapidly excreted in proportion to sodium (Beck, 1979). Conversely, a decrease in phosphate excretion and a net retention occur with release of UUO.

PATHOLOGIC CHANGES OF OBSTRUCTION

Gross Pathologic Findings

The gross pathologic changes that occur in the kidney in response to obstruction have been well described in animal models and parallel findings in humans. After 42 hours of obstruction, there is dilation of the collecting system and blunting of the papillary tips associated with an increased weight of the kidney. Collecting system dilation and renal weight further increase, and the parenchyma becomes edematous after 7 days of obstruction. Further collecting system dilation develops after 12 days of obstruction, but after 21 to 28 days the cortex and medullary tissue in the obstructed kidney become diffusely thinned. [Ladefoged and Djurhuus \(1976\)](#) demonstrated that obstructed kidneys are enlarged, with a cystic appearance but lower weight, compared to the normal contralateral kidneys 6 weeks after obstruction.

Microscopic Pathologic Findings

Urinary tract obstruction results in a progressive and eventually permanent loss in renal function. The histologic derangements associated with early obstruction are localized primarily to the tubulointerstitial compartment of the kidney and include massive tubular dilation, progressive tubulointerstitial fibrosis, inflammatory cell infiltration, and apoptotic renal tubular cell death. Although the glomeruli of the kidney are relatively spared, damage to the tubulointerstitial compartment of the kidney is quite severe ([Nagle et al, 1973](#); [Sharma et al, 1993](#); [Misseri et al, 2004](#)). Inflammatory cell infiltration occurs early in the course of obstruction ([Diamond et al, 1994, 1998](#)) and results in the release of a variety of cytokines and growth factors that stimulate fibroblast proliferation and activation and an imbalance in extracellular matrix (ECM) synthesis, deposition, and degradation. This results in an expansion of the interstitial space and a disruption in normal cellular communication ([Fig. 48-3](#)). Increasing tubular cell death accompanies progressive interstitial fibrosis ([Docherty et al, 2006](#)), and long-standing obstruction ultimately results in glomerulosclerosis ([Figs. 48-4 and 48-5](#)) most likely as a result of chronic inflammation ([Steinhardt et al, 1988](#)) and/or hyperfiltration injury ([Pascual et al, 1998](#)). Although extensive glomerulosclerosis has been shown to correlate well with a decrease in renal function in patients with obstruction, milder degrees of fibrosis and glomerulosclerosis can be seen in up to 25% of patients with obstruction and normal differential function on radionuclide imaging ([Elder et al, 1995](#)).

MOLECULAR MECHANISMS OF TUBULOINTERSTITIAL FIBROSIS

Inflammatory Cell Infiltration

Tubulointerstitial fibrosis is a major pathologic component of obstructive renal injury, and its presence contributes to obstruction-induced renal dysfunction. In fact, progressive tubulointerstitial fibrosis is the final common pathway for all kidney diseases that lead to chronic renal failure (Zeisberg and Neilsen, 2010). One of the earliest histologic changes in the obstructed kidney is an increase in inflammatory cell infiltration into the interstitial compartment of the kidney. Macrophage infiltration has been documented as early as 4 hours after the onset of renal obstruction (Schreiner et al, 1988), and the recruitment of macrophages, as well as other inflammatory cells, into the interstitial space appears to be mediated by chemokine production. All types of renal cells can express chemokines in response to immunologic, toxic, ischemic, or mechanical injury, and the interaction of chemokines with specific receptors expressed on immune cells (chemokine receptors) facilitates the migration of leukocytes and macrophages across the endothelium (Anders et al, 2003). Once these inflammatory cells populate the interstitium, they begin to elaborate a wide array of proinflammatory cytokines and growth factors that contribute to renal injury, including tumor necrosis factor- α (TNF- α) and transforming growth factor- β 1 (TGF- β 1) (Klahr and Morrissey, 2002; Misseri et al, 2004). Increased expression of chemokines has been demonstrated in response to obstruction, including monocyte chemoattractant protein-1 (MCP-1 or chemokine ligand 2 [CCL2]), macrophage inflammatory protein-1 α (MIP-1 α or CCL3), macrophage inflammatory protein-1 β (MIP-1 β or CCL4), and CCL7, and blockade of CCL2 and CCL7 has further been shown to ameliorate obstruction-induced tubulointerstitial fibrosis (Wada et al, 2004; Bani-Hani et al, 2009; Gonzalez et al, 2013). Indeed, MCP-1 has recently been identified as a potential urinary biomarker of obstruction in children with hydronephrosis (Madsen et al, 2013). Although this inflammatory cell infiltrate is certainly critical to the pathophysiology of urinary tract obstruction, cytokines and proinflammatory mediators can also be produced by renal tubular epithelial cells independent of macrophage infiltration (Kaneto et al, 1996; Misseri et al, 2004; Franke et al, 2012).

Fibroblasts and Extracellular Matrix Production

Fibroblasts in the renal interstitium are considered the primary source of ECM, and tubulointerstitial fibrosis is associated with a significant accumulation of matrix-producing fibroblasts. In response to stimulation from cytokines and growth factors, fibroblasts will secrete collagen, elastin, proteoglycans, and fibronectin into the interstitial space (Fig. 48-6). This process is normally tightly regulated by matrix metalloproteinases (MMPs), a family of enzymes responsible for tissue remodeling and the degradation of both collagenous and noncollagenous components of ECM. MMPs are excreted by a variety of cells, including fibroblasts, endothelial cells, macrophages, and lymphocytes, in an inactive form that requires further processing to become active. Control of MMP activity occurs both in the activation of the latent enzyme and with direct inhibition of the active enzyme (Ronco et al, 2007). Tissue inhibitors of MMPs (TIMPs) are produced by both tubular cells and interstitial cells in the kidney, and they function to inhibit the activity of MMPs. Dramatic increases in TIMP expression have been demonstrated in response to obstruction (Engelmyer et al, 1995; Kim et al, 2001a), and it has been postulated that increased ECM deposition during obstructive injury is due to increased TIMP inhibition of MMPs. The role of MMPs in renal fibrosis, however, appears to be much more complex than originally theorized. MMP-2 and MMP-9 have been the focus of most studies in the kidney. Although some studies demonstrate an acceleration of renal fibrosis with pharmacologic inhibition of MMP-2 and MMP-9 (Zeisberg et al, 2006), studies using MMP-9 knockout mice have

demonstrated a dramatic reduction in tubulointerstitial fibrosis in response to renal obstruction (Wang et al, 2010), and mice transgenic for MMP-2 expression (i.e., overexpression) demonstrate interstitial fibrosis, glomerulosclerosis, tubular atrophy, and renal failure in the absence of superimposed injury (Cheng et al, 2006). It appears that in addition to their degradative effect on ECM, MMPs can disrupt tubular basement membrane integrity and trigger epithelial-to-mesenchymal transition, a process that contributes to fibrosis by expanding the number of matrix-producing fibroblasts in the interstitium.

Epithelial-to-Mesenchymal Transition

Although the role of fibroblasts in renal fibrosis is well accepted, their origin and process of activation remain controversial. Resident interstitial fibroblasts, bone marrow fibroblasts, migrating leukocytes, and vascular endothelial cells are all potential sources of renal interstitial fibroblasts. Growing evidence suggests that under pathologic conditions, renal tubular epithelial cells can also undergo a phenotypic transformation into matrix-producing myofibroblasts by a process termed epithelial-mesenchymal transition (EMT) (Strutz et al, 1995; Healy and Brady, 1998; Bani-Hani et al, 2008). These activated fibroblasts acquire mesenchymal markers, migrate into the interstitial space across damaged tubular basement membranes, and become capable of producing ECM. EMT appears to be a major contributing factor to tubulointerstitial fibrosis in the obstructed kidney, and Iwano and coworkers (2002) have demonstrated that a substantial number of interstitial fibroblasts originate from tubular epithelium during renal obstruction. In fact, selective blockade of EMT in animal models impressively reduces fibrosis after obstructive injury, underscoring the importance of EMT in renal fibrogenesis (Iwano et al, 2002; Yang and Liu, 2002). A number of growth factors, cytokines, and ECM compounds regulate EMT, of which TGF- β 1 is the chief and most studied mediator. Interleukin (IL)-18 has been found to initiate and complete the entire EMT process in renal tubular epithelial cells independent of TGF- β 1 activity (Bani-Hani et al, 2009). Because EMT is a gene-directed process, it is uniquely suited to pharmacologic manipulation, which may be of great therapeutic potential in the management of patients with fibrotic renal disease.

Cytokines and Vasoactive Mediators of Fibrosis

Transforming Growth Factor- β

TGF- β 1 has long been regarded as one of the most critical mediators of obstruction-induced renal injury. Renal TGF- β 1 expression increases progressively after the onset of obstruction (Kaneto et al, 1993), and evidence indicates that TGF- β 1 is a major regulator of fibrosis via stimulation of EMT and fibroblast proliferation (Postlethwaite et al, 1987; Fan et al, 1999; Zeisberg et al, 2003), ECM synthesis (Roberts et al, 1992), and the simultaneous inhibition of collagenase and degradative MMPs (Chandrasekhar and Harvey, 1988; Border and Noble, 1994). TGF- β 1 is expressed both by macrophage and resident tubular cells, and, upon activation, TGF- β 1 will bind to its receptor and stimulate the Smad family of proteins to multimerize into a transcription-regulating complex that translocates into the nucleus and exerts TGF- β 1's biologic effects (Massague and Chen, 2000).

Bone morphogenic protein-7 (BMP-7) is a member of the TGF- β superfamily that inhibits TGF- β -dependent biologic functions (Meng et al, 2013), but the mechanism by which BMP-7 counteracts TGF- β activity remains unclear. Several studies have demonstrated that exogenous BMP-7 can not only inhibit TGF- β 1-induced EMT and renal fibrosis but actually induce mesenchymal-to-epithelial transition in adult fibroblasts and facilitate regeneration of the injured kidney (Patel and Dressler, 2005; Zeisberg et al, 2005). The BMP-7 pathway is activated after correction of renal obstruction, and activation of BMP-7 during renal recovery promotes the resolution of fibrosis and the restoration of normal renal architecture (Manson et al, 2011). Although the downstream

Figure 48-6. Mechanisms of tubulointerstitial fibrosis during renal obstruction. After infiltration of the interstitial space by activated macrophages, inflammatory mediators are released, including transforming growth factor- β 1 (TGF- β 1), tumor necrosis factor- α (TNF- α), and interleukin-18 (IL-18) that trigger renal tubular cell apoptosis, the transformation of renal tubular cells into matrix-producing fibroblasts, and further inflammatory cell infiltration. Additional fibroblasts are recruited from the bone marrow, and resident fibroblasts in the interstitial space are stimulated to secrete extracellular matrix. Angiotensin II is produced in response to the decreased renal blood flow associated with obstruction, and it further stimulates macrophage infiltration and cytokine production (TNF- α and TGF- β 1). The resulting imbalance in extracellular matrix deposition results in expansion of the interstitial space and increasing tubulointerstitial fibrosis. ECM, extracellular matrix; MMPs, matrix metalloproteinases; TIMPs, tissue inhibitors of MMPs.

mechanisms that contribute to BMP-7-mediated kidney repair remain unclear, BMP-7 has promising therapeutic potential for obstructive renal injury.

Tumor Necrosis Factor- α

TNF- α is a potent proinflammatory cytokine implicated in the pathophysiology of a wide range of renal diseases (Klahr and Morrissey, 1998; Donnahoo et al, 1999; Guo et al, 2001). TNF- α is capable of upregulating its own expression as well as the expression of other inflammatory mediators (i.e., IL-1, NO, cell adhesion molecules, eicosanoids) and can recruit and stimulate various cells in the immune system. TNF- α is produced both by resident renal tubular cells and infiltrating macrophage, and its production is increased significantly in the kidney in response to obstruction (Kaneto et al, 1996; Misseri et al 2004). TNF- α has a role in fibrotic renal injury, stimulating ECM accumulation, inhibition of ECM degradation, and upregulation of a number of cytokines and transcription factors involved in tubulointerstitial fibrosis, including TGF- β 1. Genetic deletion of the TNF- α receptor and inhibition of TNF- α pharmacologically both cause a dramatic reduction in obstruction-induced renal fibrosis (Guo et al, 1999, 2001; Meldrum

et al, 2007), and inhibition of TNF- α has been shown to reduce tubulointerstitial fibrosis even when administered late in the course of renal injury (Khan et al, 2005).

Interleukin-18

IL-18 is a recently discovered proinflammatory cytokine that has been found to be a sensitive and early marker of renal tubular damage, with urinary IL-18 levels predictive of acute tubular injury before creatinine levels and urine output become altered (Parikh et al, 2005). Liang and associates (2007) have also shown that circulating IL-18 levels and renal tubular IL-18 receptor expression is significantly increased in patients with chronic kidney disease. IL-18 expression is dramatically increased in response to obstruction, and IL-18 has been shown to directly stimulate EMT in renal tubular cells in vitro and inflammatory cell infiltration and fibrotic injury in vivo. Inhibition of IL-18 activity prevents obstruction-induced EMT, fibroblast proliferation, and fibrosis independent of TGF- β 1 and TNF- α activity, indicating that IL-18 is an important mediator of obstruction-induced renal injury through an alternative signaling mechanism (Bani-Hani et al, 2009).

Angiotensin II

The renin-angiotensin system has been implicated in the pathophysiology of obstructive uropathy because of the substantial vasoconstriction of the renal vascular bed observed during renal obstruction. Angiotensin II (AT2), a potent vasoconstrictor, is produced after conversion of AT1 to AT2 by the angiotensin-converting enzyme (ACE). AT2 production is rapidly stimulated after onset of renal obstruction and has been linked to many of the pathophysiologic processes involved in obstruction, including altered hemodynamics and renal fibrosis. AT2 upregulates TGF- β 1 and TNF- α expression during renal obstruction (Ishidoya et al, 1995; Guo et al, 2001), and ACE inhibition and inhibition of the AT2 receptor have been shown to decrease TGF- β 1 expression, ECM deposition, macrophage recruitment, and the extent of obstruction-induced renal fibrosis (Klahr and Morrissey, 1997; Morrissey and Klahr, 1998; Guo et al, 2001). AT2 also has been implicated in the perturbation of interstitial capillary circulation that occurs in fibrotic renal disease, resulting in chronic renal hypoxia and further stimulation of EMT and cytokine production (Norman et al, 2003; Zeisberg and Neilson, 2010). Indeed, angiotensin inhibition currently represents the principal clinical therapeutic approach to slowing or preventing the progression of most forms of renal disease (Chevalier et al, 2009).

Apoptosis

Apoptosis, or programmed cell death, is the major mechanism by which renal tubular cell death and a reduction in renal mass occur after renal obstruction (Gobe and Axelsen, 1987; Truong et al, 1998). Apoptosis is present in both normal and disease states and can be triggered by either a death receptor signaling pathway (i.e., TNF- α binding to its receptor) or an intrinsic pathway involving disturbances in the mitochondrial membrane and release of cytochrome *c*. After stimulation of either of these signaling pathways, caspases (cysteiny l aspartate-specific proteinases), which are a family of 12 enzymes that act as the effector molecules for apoptosis, become activated. Caspases function to cleave various nuclear and cytoplasmic substrates, resulting in nuclear fragmentation and condensation. The cell is then broken down into multiple membrane-bound spherical bodies, called apoptotic bodies, which are phagocytized by adjacent healthy cells. Compared to necrosis, this unique mechanism of cell death maintains cell membrane integrity and thereby minimizes the involvement of inflammatory scavenger cells and the overall inflammatory response (Wyllie et al, 1980). Renal tubular and interstitial cells are most susceptible to apoptotic cell death during renal obstruction (Truong et al, 1998). Choi and colleagues (2000) demonstrated renal tubular cell apoptosis beginning after 4 days and peaking after 15 days of renal obstruction, whereas interstitial cell apoptosis increased progressively over the duration of renal obstruction. Glomerular cells, on the other hand, appear to be very resistant to obstruction-induced apoptosis, with no evidence of glomerular cell apoptosis occurring after 90 days of renal obstruction (Truong et al, 1998).

Many of the cytokines and vasoactive factors implicated in EMT and tubulointerstitial fibrosis also appear to mediate apoptotic cell death in response to renal obstruction, in part by increasing caspase expression and activation. TGF- β 1 directly stimulates renal tubular cell apoptosis in vitro (Schuster and Kriegelstein, 2002; Yang et al, 2006), and TGF- β 1 inhibition has been shown to prevent obstruction-induced and stretch-induced renal tubular cell apoptosis (Miyajima et al, 2000, 2001a). TNF- α is a directly cytotoxic cytokine that induces apoptosis in many cells, including renal tubular cells, through interactions with its membrane-bound receptors, TNFR1 and Fas. The expression of TNF-related apoptotic molecules (i.e., TNFR1 and Fas) increases in parallel to observed increases in obstruction-induced tubular cell apoptosis (Choi et al, 2000), and TNF- α neutralization has been shown to ameliorate obstruction-induced apoptosis and pro-apoptotic signaling (Misseri et al, 2005). IL-18 has similarly been demonstrated to be an important mediator

of renal tubular cell apoptosis both in vitro and in response to UUO (Zhang et al, 2011). The effect of AT2 on obstruction-induced apoptosis is less clear. Morrissey and Klahr (1999) demonstrated that an AT2 type 2 receptor antagonist inhibits obstruction-induced apoptosis, but other investigators have found no benefit of either ACE inhibitors or AT2 type 2 receptor antagonists in preventing obstruction-induced apoptosis (Chevalier et al, 1999a; Radovic et al, 2008). These diverging cellular responses to a single stimulus suggest that renal tubular epithelial cells may undergo an adaptive (EMT) versus death (apoptosis) response depending on the degree or duration of stimulation.

CLINICAL IMPACT OF RENAL OBSTRUCTION

Hypertension

Hypertension can develop in response to urinary tract obstruction and is more common in the presence of BUO than in the presence of UUO. Vaughan and Gillenwater (1973) noted hypertension in 17 of 22 patients with BUO that was reversible on relief of obstruction in all but 2 patients. Increased ANP levels and intravascular volume have been documented in patients with BUO and suggest a volume-mediated mechanism for hypertension in these patients. Hypertension is less common in patients with UUO (Vaughan and Sosa, 1990) and does not appear to be related to volume overload because the normal contralateral kidney is able to eliminate excess volume and solutes. The renin-angiotensin system is upregulated in response to UUO and has been implicated as the mechanism of hypertension in these patients. Previous studies have demonstrated that blockade of the AT2 type 2 receptor with losartan prevents the rise in systolic blood pressure associated with UUO and normalizes systolic blood pressure in chronically hypertensive UUO rats (el-Dahr et al, 1993). Hypertension is therefore more likely to occur in response to BUO and more likely to be reversed after relief of obstruction in patients with BUO compared to UUO.

Compensatory Renal Growth

First described by Hinman in 1943, compensatory renal growth refers to the development of increased volume of the contralateral kidney in response to UUO or renal agenesis (Taki et al, 1983; Peters et al, 1993). The development of contralateral renal growth is influenced by age and the degree and duration of obstruction. Studies in human patients who underwent nephrectomy demonstrated that a reduction in renal compensatory growth occurs with increasing age (Edgren et al, 1976). Compensatory renal growth appears to be directly proportional to the duration of obstruction and is less prominent with partial rather than complete UUO (Chevalier and Kaiser, 1984; Chevalier et al, 1987, 1999b; Eskild-Jensen et al, 2001). Interestingly, a recent study also demonstrated that compensatory renal growth, renal hypertrophy, and GFR are increased in response to unilateral nephrectomy in male rats as compared to female rats or gonadectomized groups (Azurmendi et al, 2013), suggesting that sex hormones have a role in this adaptive response as well. While the kidney enlarges, an increase in the number of nephrons or glomeruli does not occur, indicating that the increase in renal volume is primarily a consequence of cellular hypertrophy rather than hyperplasia (Peters et al, 1993). A recent study in fetal sheep, however, demonstrated that animals subjected to $\frac{3}{4}$ nephrectomy had increased cortical thickness, tubular hypertrophy, and a lower glomerular density but a striking increase in glomerular number compared to animals subjected to $\frac{1}{2}$ nephrectomy. Furthermore, the magnitude of the regenerative process appeared to be more dependent on the severity of renal reduction than on the timing of renal reduction (Sammur et al, 2013). This adaptive response allows the remaining kidney to ensure homeostasis and compensate for the lack of functioning contralateral renal tissue; however, the mechanisms behind compensatory renal growth remain poorly understood.

Insulin-like growth factor (IGF-1) appears to be an important mediator of compensatory renal hypertrophy (Cleper, 2012). IGF-1

is a growth factor that has a critical role in renal development, growth, and function (Kamenicky et al, 2014). Exogenous IGF-1 has been shown to increase GFR in normal humans (Guler et al, 1989) and attenuate renal injury resulting from obstruction in animals (Chevalier et al, 2000). IGF-1 levels are significantly elevated in the contralateral kidney after unilateral nephrectomy or UUO (Serel et al, 2000), and evidence suggests that IGF-1 expression may be increased in immature kidneys compared to mature kidneys after unilateral nephrectomy (Mulroney et al, 1992). Significant increases in serum IGF-1 levels have also been demonstrated in humans after donor nephrectomy, and IGF-1 levels have been positively correlated with the increased renal volume demonstrated on postoperative imaging after donor nephrectomy (Nam et al, 1999). Other growth factors have been implicated as effectors of this process (i.e., TGF- β 1, hepatocyte growth factor); however, the sensors of reduced renal mass that stimulate compensatory renal hypertrophy remain unknown.

TREATMENT OF RENAL OBSTRUCTION

Pain Management

The first-line approach for the patient presenting with renal colic is the administration of analgesics. Opioids have a rapid onset of analgesia but may promote nausea and emesis, cause excessive sedation, and have the potential to be abused. NSAIDs are nonopioid analgesics that—unlike opioids—target the inflammatory basis of pain. Renal colic is thought to arise from increased collecting system pressure and an acute distention of the collecting system (Holmlund, 1983), and NSAIDs have been demonstrated to reduce collecting system pressure. Indomethacin and other NSAIDs cause a decrease in renal pelvic pressure in response to obstruction (Sjodin et al, 1982; Gasparich and Mayo, 1986; Frøkiaer et al, 1993) that is thought to be mediated by a reduction in RBF. Perlmutter and associates (1993) demonstrated that ketorolac induces a prompt reduction in both RBF and intrapelvic pressure in canines with UUO. COX-2 inhibitors are a form of NSAID that block the synthesis of prostaglandins from arachidonic acid. It has previously been shown that COX-2 inhibitors can prevent PGE-mediated downregulation of AQP channels and major sodium channels in response to obstruction (Norregaard et al, 2005), and the resulting decrease in hydrostatic pressure within the tubules may provide an additional mechanism for the NSAID-mediated reduction in intrapelvic pressures.

In clinical trials, NSAIDs have proved to be superior to opioids in managing renal colic and are associated with a greater reduction in pain scores, less need for “rescue” analgesia, and less emesis than with opioids (Holdgate and Pollock, 2004). NSAIDs should not be used in patients with renal insufficiency, however, because renal dysfunction can be exacerbated by the decrease in RBF induced by NSAIDs. COX-1 inhibitors also should not be used in patients at risk for gastrointestinal bleeding or when optimal platelet function is needed, and COX-2 inhibitors have been linked to an increased risk for myocardial infarction and stroke as a result of an adverse effect on blood vessels (Cannon and Cannon, 2012). Although opioids have untoward side effects, they still provide excellent analgesia and remain an important tool in the management of the patient with renal colic. The α_1 -blocker Flomax has been used for medical expulsive therapy, and studies have demonstrated the ability of α_1 -blockers to facilitate stone passage and reduce the requirement for analgesics (Wang et al, 2008).

Renal Drainage

Prompt drainage of the obstructed kidney is important to relieve pain and prevent functional decline. Minimally invasive endourologic and interventional radiologic techniques allow for temporary drainage until a definitive procedure can be performed, and in some circumstances it may be a permanent management option. Urine cultures should be obtained from the obstructed renal unit at the

time of relief of obstruction when infection is suspected, and antibiotic therapy should be instituted. Ureteral obstruction that is symptomatic, accompanied by fever, complicated by undrained infection, or determined to be high grade, bilateral, or inducing renal failure warrants immediate drainage.

Both percutaneous nephrostomy tubes and internal stents have been shown to be equally effective in relieving an obstructed collecting system with similar complication rates (Regalado, 2006). Percutaneous nephrostomy tubes are larger caliber and offer the advantage of providing superior drainage, especially if the fluid is more purulent. The catheters can be irrigated to prevent clogging, the urine output of the kidney can be measured, and excessive ureteral manipulation can be avoided, decreasing the risk for sepsis or rupture. The procedure can also be done using ultrasound guidance with local anesthesia and conscious sedation, eliminating the need for an anesthesiologist and ionizing radiation exposure. Internal stents offer the advantage of increased patient comfort with no catheter extending out of the flank, and a lower potential risk for bleeding complications. Therefore internal stent placement should be considered first for patients that are coagulopathic. If thick purulent fluid is obtained from the kidney at the time of ureteral stenting, placement of a large-diameter stent is recommended and/or placement of a diversion stent that can be irrigated and monitored. Internal stent placement typically requires greater x-ray exposure than percutaneous nephrostomy placement, which may be of concern in pregnant patients (Mokhmali et al, 2001; McAleer and Loughlin, 2004), and accelerated stent encrustation in this patient population resulting from increased calcium excretion may increase the risk for stent failure (Goldfarb et al, 1989).

Historically, ureteral stenting has not been very effective for treating patients with extrinsic ureteral obstruction. Docimo and Dewolf (1989) reported a 43% failure rate in stents placed for extrinsic obstruction, the majority related to malignancy, and Chung and colleagues (2004) similarly identified a 42% rate of stent failure in these patients, with a diagnosis of cancer, metastatic disease requiring chemotherapy or radiation, and renal insufficiency predictors of stent failure. New metallic stents composed of a unique continuous unfenestrated coil of nonmagnetic alloy have proved to be safe and effective for patients with extrinsic compression of the ureter and offer longer indwelling times (3.5 to 11 months). Age and preoperative serum creatinine levels have been identified as independent risk factors for metallic stent failure, and lower gastrointestinal tract cancers have been associated with longer metallic stent duration times than genitourinary cancers (Chow et al, 2014).

Renal Recovery after Obstruction

The duration and severity of obstruction has a significant influence on renal functional recovery. When acute complete ureteral obstruction is promptly relieved, full recovery of global GFR can occur, but longer periods of complete ureteral obstruction are associated with diminished return of GFR. The persistent decrease in GFR and RBF after relief of obstruction is due to persistent vasoconstriction of the afferent arteriole. Vaughan and Gillenwater (1971) performed some of the initial studies on recovery of renal function after obstruction. In a canine model of UUO, they noted that full recovery of renal function occurred after 7 days of UUO whereas only 70% recovery of GFR occurred after 14 days of UUO, 30% after 4 weeks of UUO, and none after 6 weeks of UUO. More recent studies demonstrated that renal damage can persist despite recovery of renal function. After 3 days of UUO in a rat model of obstruction, GFR and RBF returned to baseline levels within 14 days in the previously obstructed kidney (Ito et al, 2004), but interstitial fibrosis and tubular apoptosis continued to increase after relief of obstruction. Mouse studies suggest that after 7 days of obstruction, normal renal function is not restored in the previously obstructed kidney even after 30 days of recovery, with GFR and RBF reduced by 40% and the urine albumin-to-protein ratio increased by 2.8-fold. The remaining intact nephrons are hypertrophied, and there

is evidence of substantial glomerular injury (Chaabane et al, 2013). In humans, delayed relief of obstruction (>2 weeks) has been demonstrated to decrease long-term renal function and increase the risk for hypertension (Lucarelli et al, 2013).

Other factors that influence the return of renal function after relief of obstruction include a lesser degree of obstruction, greater compliance of the collecting system, and the presence of pyelolymphatic backflow (Shokeir et al, 2002). Conversely, older age and decreased cortical thickness are predictors of diminished recovery of renal function after relief of obstruction (Lutaif et al, 2003). The presence of increased collagen deposition in renal parenchyma at the time of pyeloplasty has been shown to have a negative impact on recovery of renal function, because it demonstrates a more advanced state of renal fibrosis (Kim et al, 2005; Kiratli et al, 2008). Relief of obstruction is also different with BUO than with UUUO. As a result of the increased volume expansion, accumulation of urea and other osmolytes, and increased levels of ANP, a profound diuresis and natriuresis accompanies relief of BUO as opposed to UUUO. In addition, patients with BUO or obstruction of a solitary kidney are at risk for chronic urinary acidification and concentrating defects (Berlyne, 1961).

Thompson and Gough (2001) demonstrated that dimercaptosuccinic acid (DMSA) is superior to Mag3 and DTPA in measuring function of the obstructed kidney and predicting the ultimate outcome of surgical intervention. Mag3 was found to underestimate the potential of the kidney for recovery and was associated with a large variation in accuracy. The superiority of DMSA in assessing function under these circumstances appears to be related to its fixation to the renal cortex and delayed clearance. In cases in which renal function is significantly depressed on diuresis renography and nephrectomy is being considered, a preoperative DMSA scan may be of additional value in surgical planning.

Choice of Surgical Intervention

Definitive management of urinary tract obstruction is based on the cause of obstruction, status of the contralateral kidney, function of the affected kidney, and patient's age and overall medical status. A number of different endoscopic, open, laparoscopic, and robotically assisted ablative and reconstructive options are available and are discussed elsewhere in this text. In general, a nephrectomy should be considered for an obstructed kidney that contributes less than 10% to the patient's overall renal function. The decision to remove a kidney, however, should be made only after the kidney has been adequately drained for a sufficient period to allow maximal recovery and an accurate assessment of renal function (Kerr, 1954). In the setting of global renal insufficiency, the decision is more complicated and patients may elect management with a chronic indwelling stent or nephrostomy tube to prevent more rapid progression to dialysis.

Postobstructive Diuresis

Mechanism of Postobstructive Diuresis

Postobstructive diuresis, defined as a period of significant polyuria, may develop after the relief of urinary tract obstruction. Urine outputs of 200 mL/hr or greater may be encountered. Although this primarily occurs after relief of BUO, it can occur rarely in the presence of a normal contralateral kidney (Schlossberg and Vaughan, 1984). The diuresis is generally a physiologic response to the accumulated solutes and volume expansion that have occurred during obstruction. Sodium, urea, and free water are eliminated, and the diuresis subsides after homeostasis is achieved (Loo and Vaughan, 1985).

Pathologic postobstructive diuresis may ensue, characterized by inappropriate renal handling of water and/or solutes. Downregulation of sodium transport channels (Li et al, 2003), downregulation of AQP channels (Li et al, 2001), poor responsiveness of the collecting duct to vasopressin, and altered regulation

of ANP (Kim et al, 2001b) can result in a disruption of the medullary interstitial solute gradient and profound diuresis and natriuresis.

Clinical Management of Postobstructive Diuresis

The majority of patients do not demonstrate a clinically significant postobstructive diuresis after relief of urinary tract obstruction, and those who are susceptible typically exhibit signs of fluid overload, including edema, congestive heart failure, and hypertension (Loo and Vaughan, 1985). Most commonly, postobstructive diuresis develops after relief of urinary retention, and the speed at which the bladder is drained has not been shown to have any effect on the development of postobstructive diuresis or hematuria (Nyman et al, 1997).

After relief of obstruction, patients with BUO or an obstructed solitary kidney should be monitored for the development of postobstructive diuresis. Patients with normal renal function, normal electrolytes, no evidence of fluid overload, and a normal mental status should have their vital signs and urine output monitored regularly, and they should be given free access to oral fluids. If evidence of a postobstructive diuresis develops, vital signs, urine output, and electrolytes should be monitored more frequently, and patients should continue to have free access to oral fluids. Generally, patients with a normal mental status should not be given IV fluids because this may prolong the period of diuresis. This is a physiologic diuresis that, in the majority of cases, resolves when free water and excess solutes are eliminated. In patients with impaired renal function, altered mental status, and signs of fluid overload, more intense monitoring is indicated. A urine osmolality should be checked, and vital signs and urine output should be checked frequently. Electrolytes should be monitored every 12 hours or more often if necessary. Patients with poor cognitive function should be given IV fluids, although at a rate below maintenance. If pathologic diuresis ensues, the patient can become hypovolemic as a result of excess water loss, and electrolyte abnormalities may develop as result of salt or potassium wasting. Very intense monitoring and careful fluid and electrolyte replacement are indicated in these patients. The urine is usually isosthenuric initially, and IV fluid replacement with 0.45% saline administration at a rate lower than the urine output is recommended (Frøkiaer and Zeidel, 2007). Changes in the type and amount of IV fluid administration are based on the patient's clinical status, serum, and urinary electrolytes.

Experimental Modulation of Postobstructive Diuresis

Experimental data suggest the potential for pharmacologic manipulation of postobstructive diuresis. It remains unclear, however, what role pharmacologic manipulation might play in clinical practice. As discussed previously, BUO is associated with increased COX-2 expression, and selective COX-2 inhibition prevents the downregulation of AQP2 channels in response to obstruction (Norregaard et al, 2005). Norregaard and colleagues (2007) demonstrated that COX-2 activity increases in the postobstructive phase and that this contributes to polyuria and an impaired urine-concentrating ability. After administration of a selective COX-2 inhibitor, the authors demonstrated that urine output was reduced but sodium excretion and GFR remained unchanged 24 hours after release of BUO. Evidence also exists that sildenafil citrate (Viagra) can induce accumulation of AQP2 channels in collecting duct cells in vitro, independent of vasopressin stimulation, by activating a parallel pathway mediated by cyclic guanosine monophosphate (Bouley et al, 2005). Clearly, further research is required to identify effective management strategies for postobstructive diuresis and to determine which patients would benefit from pharmacologic manipulation.

Evaluation of Upper Tract Obstruction

Ureteropelvic Junction Obstruction

Retrocaval Ureter

Ureteral Stricture Disease

Ureteroenteric Anastomotic Stricture

Retroperitoneal Fibrosis

Technologic advances continue to evolve both the diagnostic and therapeutic alternatives available in the contemporary management of upper urinary tract obstruction. The obstructive processes may be intrinsic, extrinsic, congenital, or iatrogenic, and in many patients the cause of obstruction may not be immediately evident. Furthermore, making an accurate diagnosis of obstruction can be challenging.

The treatments for upper tract obstruction range from ureteral stent placement to complex procedures involving ileal interposition or autotransplantation. Myriad skills are required for total surgical management of upper urinary tract obstruction. Not surprisingly, endourology, laparoscopy, and robotics continue to be more prominent in the surgical management of upper urinary tract obstruction. As a result of the wide array of available treatments, the urologist must have an understanding of the indications and risks of all the alternatives.

This chapter provides a state-of-the-art presentation of the diagnostic and therapeutic management strategies for patients with upper urinary tract obstruction. The chapter is organized by the anatomic location of obstruction. The etiology, diagnosis, indications for intervention, risks, and therapeutic options (including endoscopic, laparoscopic, robotic, and open approaches) are thoroughly reviewed.

EVALUATION OF UPPER TRACT OBSTRUCTION

The increasing use of computed tomography (CT) scanning in emergency departments and for various screening purposes has led to frequent suspicion of upper tract obstruction (Davis, 2012). Moreover, the widespread use of low-dose CT scans, which are often of lower resolution, may necessitate follow-up imaging (Zagoria and Dixon, 2009). After low-dose CT, the urologist can use ultrasound, excretory urography, diuretic renography, CT urography, retrograde pyelography, Whitaker tests, and ureteroscopy to delineate the precise cause and subsequent treatment strategy of upper tract obstruction. For each specific disorder presented here, we will discuss the recommended approach to the upper tract evaluation.

URETEROPELVIC JUNCTION OBSTRUCTION

The diagnosis of ureteropelvic junction (UPJ) obstruction (UPJO) describes a functionally significant impairment of urinary transport from the renal pelvis to the ureter. Although most cases are congenital, the problem may not become clinically apparent until much later in life (Jacobs et al, 1979). Acquired conditions such as stone disease, postoperative or inflammatory stricture, or urothelial neoplasm may also manifest clinically with symptoms and signs of obstruction at the level of the UPJ. Similarly, extrinsic obstruction can occur at this level as well. This section focuses primarily on the

diagnosis and treatment of “congenital” UPJO, although these techniques may be applied to the management of certain acquired conditions, in particular urinary stones.

Pathogenesis

Congenital UPJO typically results from intrinsic disease. A frequently found defect is the presence of an aperistaltic segment of the ureter, perhaps similar to that found in primary obstructive megaureter. In these cases, histopathologic studies reveal that the spiral musculature normally present has been replaced by abnormal longitudinal muscle bundles or fibrous tissue (Allen, 1970; Foote et al, 1970; Hanna et al, 1976; Gosling and Dixon, 1978) (Fig. 49-1). This results in failure to develop a normal peristaltic wave for propagation of urine from the renal pelvis to the ureter. Recognition that this type of segmental defect is often responsible for UPJO is of utmost importance clinically because such ureters may appear grossly normal at the time of surgery and, in fact, may often be calibrated to 14 Fr or greater. Further investigations in the cause of UPJO have shown decreased density of interstitial cells of Cajal at the UPJ in children, but less so in cases involving solely intrinsic UPJO (Solari et al, 2003; Koleda et al, 2012). In addition, the cytokine produced in the urothelium has also been proposed to exacerbate UPJO (Chiou et al, 2005). Other experimental studies have implicated transforming growth factor- β , epidermal growth factor expression, nitric oxide, and neuropeptide Y in UPJ stenosis (Knerer et al, 2001; Yang et al, 2003). A less frequent intrinsic cause of congenital UPJO is true ureteral stricture. Such congenital ureteral strictures are most frequently found at the UPJ, although they may be located at sites anywhere along the lumbar ureter. Abnormalities of ureteral musculature have been implicated as electron microscopy has demonstrated excessive collagen deposition at the site of the stricture (Hanna et al, 1976).

Intrinsic obstruction at the UPJ may also result from kinks or valves produced by infoldings of the ureteral mucosa and musculature (Maizels and Stephens, 1980). In these patients the obstruction may actually be at the level of the proximal ureter. This phenomenon appears to result from retention or exaggeration of congenital folds normally found in the ureter of developing fetuses. In some of these patients the defects are bridged by ureteral adventitia. Grossly, this can manifest as external bands or adhesions that appear to be causing the obstruction. In fact, Johnston and colleagues in 1977 reported that lysis of external adhesions can at times reestablish flow without pyeloplasty (Johnston et al, 1977). In the majority of patients, however, these bands or adhesions are likely to be a secondary phenomenon associated with intrinsic obstruction, so operative pyeloplasty would usually be most effective. The presence of these kinks, valves, bands, or adhesions may also produce angulation of the ureter at the lower margin of the renal pelvis in such a manner that as the pelvis dilates anteriorly and inferiorly, the ureteral insertion is carried further proximally. In these patients the

Figure 49-1. The microphotograph is taken through the ureteropelvic junction. There is marked attenuation of smooth muscles and smooth muscle in disarray and hypertrophy surrounding the urothelial lining.

most dependent portion of the pelvis is inadequately drained and the apparent high insertion of the ureteral ostium is actually a secondary phenomenon (Kelalis, 1976). In at least some patients, however, the high insertion itself is likely the primary obstructing lesion because this phenomenon is found more frequently in the presence of renal ectopia or fusion anomalies (Zincke et al, 1974; Das and Amar, 1984). Thus a high insertion can have implications in the subsequent surgical management, particularly endourologic approaches.

Controversy persists regarding the potential role of “aberrant” vessels in the etiology of UPJO. Significant crossing vessels have been noted in up to 63% of patients with UPJO but in as little as 20% of individuals with normal kidneys (Quillin et al, 1996; Zeltser et al, 2004; Richstone et al, 2009). Although these lower pole vessels have often been referred to as aberrant, these segmental vessels, which may be branches from the main renal artery or arise directly from the aorta, are usually normal variants (Stephens, 1982). In some patients, these lower pole vessels cross the ureter posteriorly and truly have an aberrant course. Historically, it has been believed that the associated vessel alone does not cause the primary obstruction (Hanna, 1978). In fact, the true cause is an intrinsic lesion at the UPJ or proximal ureter that causes dilation and ballooning of the renal pelvis over the polar or aberrant vessel. Recent studies using three-dimensional (3D) multidetector row CT demonstrated that the precise location of crossing vessels did not correspond to the obstructive transition point in patients with UPJO (Lawler et al, 2005). In contrast, one group found improvement in patients undergoing only ligation of crossing vessels (Keeley et al, 1996). Richstone and colleagues reviewed histopathology from 95 patients with UPJO and found that 43% of 65 patients with a crossing vessel had no intrinsic abnormality (Richstone et al, 2009). Regardless, the presence of crossing vessels most certainly has a detrimental effect on the success rates of endopyelotomy (Van Cangh et al, 1994; Nakada et al, 1998). UPJO with concomitant anatomic anomalies such as horseshoe kidney and pelvic kidney also present surgical challenges. Notably, the emphasis on laparoscopic and robotic pyeloplasty has quelled the interest in the relevance of preoperative assessment of crossing vessels because this can be addressed at the time of reconstruction.

UPJO may also result from acquired lesions. In children, vesico-ureteral reflux can lead to upper tract dilation with subsequent elongation, tortuosity, and kinking of the ureter. In some patients these changes may only mimic the radiographic findings of true UPJO. However, true UPJO can definitely coexist with vesicoureteral reflux, although it may be difficult to determine whether the anomalies are merely coincident or whether the upper tract ureteral obstruction has resulted from the reflux (Lebowitz and Johan,

1982). Diuretic renography is the first-line modality for differentiating between UPJO and reflux. Other acquired causes of obstruction at the UPJ include benign lesions such as fibroepithelial polyps (Berger et al, 1982; Macksood et al, 1985), urothelial malignancy, stone disease, and postinflammatory or postoperative scarring or ischemia. For these acquired diseases, the techniques discussed in this section may be useful adjuncts for management of the obstruction as long as the primary problem is also addressed where appropriate. For instance, fibroepithelial polyps can be managed using retrograde ureteroscopy and holmium laser excision (Lam et al, 2003a).

Patient Presentation and Diagnostic Studies

UPJO, although most often a congenital problem, can manifest clinically at any time of life. Historically, the most common presentation in neonates and infants was the finding of a palpable flank mass. However, the current widespread use of maternal prenatal ultrasonography has led to a dramatic increase in the number of asymptomatic newborns being diagnosed with hydronephrosis, many of whom are subsequently found to have UPJO (Bernstein et al, 1988; Wolpert et al, 1989). A fraction of cases may also be found during evaluation of azotemia, which may result from bilateral obstruction in a functionally or anatomically solitary kidney. UPJO may also be incidentally found during studies performed to evaluate unrelated anomalies such as congenital heart disease (Roth and Gonzales, 1983). In older children or adults, intermittent abdominal or flank pain, at times associated with nausea or vomiting, is a frequent presenting symptom. Hematuria, either spontaneous or associated with otherwise relatively minor trauma, may also be an initial symptom. Laboratory findings of microhematuria, pyuria, or frank urinary tract infection might also bring an otherwise asymptomatic patient to the urologist. Rarely, hypertension may be a presenting finding (Riehle and Vaughan, 1981).

Radiographic studies should be performed with a goal of determining both the anatomic site and the functional significance of an apparent obstruction. Although excretory urography remains a reasonable option for radiographic diagnosis, this study is rarely used today. Classically, excretory urographic findings include delay in function associated with a dilated pelvicalyceal system. If the ureter is visualized, it should be of normal caliber. In some patients, symptoms may be intermittent and urography findings between painful episodes may be normal. In such cases the study should be repeated during an acute episode when the patient is symptomatic (Nesbit, 1956). Provocative testing with diuretic urography may allow accurate diagnosis in select patients. The patient should be well hydrated and the study then performed after injection of furosemide, 0.3 to 0.5 mg/kg (Malek, 1983) (Fig. 49-2).

CT scan is usually obtained for any patient with acute flank pain (Fielding et al, 1997; Dalrymple et al, 1998; Vieweg et al, 1998) (Fig. 49-3). Moreover, contrast-enhanced CT scans provide detailed anatomic and functional information to aid in diagnosis of UPJO (Fig. 49-4). Both ultrasonography and CT scanning also have a role in differentiating acquired causes of obstruction such as radiolucent calculi or urothelial tumors. In neonates and infants, the diagnosis of UPJO has usually been suggested either by routine performance of maternal ultrasonography or by the finding of a flank mass. In either setting, renal ultrasonography is usually the first radiographic study performed. Ideally, ultrasonography should be able to visualize dilation of the collecting system to help differentiate UPJO from multicystic kidney and determine the level of obstruction. UPJO and multicystic kidneys are distinguishable in the majority of patients by ultrasound alone. With UPJO, the pelvis is visualized as a large, medial sonolucent area surrounded by smaller, rounded sonolucent structures representing dilated calyces. At times, dilated calyces will be seen connecting to the pelvis via dilated infundibula (Fig. 49-5). More recently, Dias and colleagues have shown that prenatal renal pelvis dilation can predict the need for surgical repair of the UPJ (Dias et al, 2013).

Figure 49-2. A, This patient with intermittent left flank pain underwent intravenous urography. The calyces are sharp bilaterally without evidence of obstruction. However, there is a “box-shaped” pelvis on the left side, which may be associated with intermittent obstruction. B, This intravenous urogram in the same patient was performed along with injection of intravenous furosemide, which brought out the obvious left-sided ureteropelvic junction obstruction. The patient’s symptoms were subsequently relieved with a left pyeloplasty.

Figure 49-3. Noncontrast computed tomography scan performed as the initial radiographic study in a patient with left flank pain revealed hydronephrosis to the level of the ureteropelvic junction (UPJ). No calculus was visualized, and a presumed diagnosis of UPJ obstruction was considered. This proved correct on subsequent radiographic studies.

Occasionally, a solid-appearing renal cortex can be seen surrounding the sonolucent areas or separating the dilated calyces. In contrast, the cysts of multicystic kidneys are visualized as various-sized sonolucent areas in random distribution. Although the cysts may be connected, this is rarely visualized sonographically.

Furthermore, little solid tissue is seen, and what is present has a random distribution among the cysts. Rarely a large, centrally located cyst may cause confusion in the diagnosis (King et al, 1984a). In this setting, a renal scan should be performed. Specifically, a technetium Tc99m-diethylenetriaminedipentaacetic acid (^{99m}Tc -DTPA) scan allows differentiation of these two entities. Multicystic kidneys rarely reveal concentration of this isotope. When uptake is seen, the areas of functioning tissue are initially discrete and are usually medial to the bulk of the mass, which itself remains a “cold” area. In contrast, neonatal kidneys with UPJO usually exhibit good concentration of the isotope. Furthermore, even with severe obstruction in which only a cortical rim remains, uptake of the isotope will be seen peripherally in the cortex, again helping to differentiate this from multicystic kidney (King et al, 1984a).

Diuretic renography is effective in predicting recovery of function in cases in which intravenous urography has revealed nonvisualization. Diuretic renography allows quantification of the degree of obstruction and can help differentiate the level of obstruction. Today, ^{99m}Tc -mercaptoacetyl triglycine (^{99m}Tc -MAG3, or MAG3) is the preferred isotope over ^{99m}Tc -DTPA or radioiodinated Hippuran because of favorable imaging and dosimetry considerations (Roarke and Sandler, 1998). Diuretic renography remains a commonly used study for diagnosing both UPJ and ureteral obstruction because it provides quantitative data regarding differential renal function and obstruction, even in hydronephrotic renal units. Diuretic renography is noninvasive and readily available in most medical centers. Ideally, diuretic renography can be used to follow patients for functional loss, most effectively when a standard protocol is used. The diuretic is given 20 minutes into the study to allow time for filling of the collecting system. One study found

Figure 49-4. A, Contrast-enhanced computed tomography scan identifies a classic ureteropelvic junction (UPJ) appearance in early-phase imaging. B, Early images reveal normal nephrogram and delayed filling of the obstructed, dilated UPJ. C, Delayed images demonstrate holdup of contrast drainage on the right compared with the normal left side.

Figure 49-5. Classic ultrasound image of ureteropelvic junction obstruction, with dilated renal pelvis and infundibula and calyces. The ureter is not visualized in this image.

diuretic renography to be useful in children to rule out concomitant UPJO with associated high-grade reflux (Stauss et al, 2003). There is evidence that diuretic renography using MAG3 is a most accurate study for patients with UPJO after therapeutic intervention (Niemczyk et al, 1999) (Fig. 49-6).

The diagnosis of UPJO can generally be made with a high degree of certainty on the basis of the clinical presentation and the results of any one or more of the imaging studies already cited. It is preferable to have a combination of anatomic and functional studies, such as retrograde pyelogram and diuretic renography, to best plan therapy. Retrograde pyelography thus retains a role for confirmation of the diagnosis and for demonstration of the exact site and nature of obstruction before repair. In most cases, this study is performed at the time of the planned operative intervention to avoid the risk of introducing infection in the face of obstruction. However, retrograde pyelography is indicated emergently whenever the UPJO requires acute decompression, such as in the setting of infection or compromised renal function. If cystoscopic retrograde manipulation has been unsuccessful or may be hazardous, particularly in neonates or infants, placement of a percutaneous nephrostomy is preferred. This allows the performance of antegrade studies that will help define the nature and exact anatomic site of obstruction. It also allows decompression of the system in patients with associated infection or compromised renal function and allows assessment of recoverability of renal function after decompression. When there remains some

doubt as to the clinical significance of a dilated collecting system, placement of a percutaneous nephrostomy tube allows access for dynamic pressure perfusion studies. First described by Whitaker in 1973, the renal pelvis is continuously perfused at 10 mL/min with normal saline solution or dilute radiographic contrast solution under fluoroscopic control. Renal pelvic pressure is monitored during the infusion, and the pressure gradient across the UPJ is determined. During the infusion, the bladder is continuously drained with an indwelling catheter to prevent transmission of intravesical pressures. Renal pelvic pressure ranging up to 12 to 15 cm H₂O during this infusion suggests a nonobstructed system. In contrast, pressures in excess of 15 to 22 cm H₂O are highly suggestive of a functional obstruction. Pressures between these extremes may be nondiagnostic (O'Reilly, 1986).

Although pressure perfusion studies can often provide valuable information regarding the functional significance of an apparent obstruction, these studies can at times be inaccurate. This inaccuracy may be a result of variations in renal pelvic anatomy and compliance (Koff et al, 1986) or positional variations (Ellis et al, 1995). The urologist must collate the clinical presentation and results of all diagnostic studies performed to identify the best clinical intervention.

Indications and Options for Intervention

Contemporary indications for intervention for UPJO include the presence of symptoms associated with the obstruction, impairment of overall renal function or progressive impairment of ipsilateral function, development of stones or infection, or, rarely, causal hypertension. The primary goal of intervention is relief of symptoms and preservation or improvement of renal function. Traditionally, such intervention should be a reconstructive procedure aimed at restoring nonobstructed urinary flow. This is especially true for neonates, infants, or children in whom early repair is desirable because these patients will have the best chance for improvement in renal function after relief of obstruction (Bejjani and Belman, 1982; Roth and Gonzales, 1983; Wolpert et al, 1989). However, timing of the repair in neonates remains controversial (DiSandro and Kogan, 1998; Koff, 1998; Hanna, 2000; Koff, 2000; Shokeir and Nijman, 2000), mostly because of difficulty in defining those kidneys truly at risk for functional obstruction. In a prospective study of 104 neonates with primary unilateral hydronephrosis suspected of being caused by UPJO, after a mean follow-up of 21 months, only 7 (7%) required pyeloplasty for functional obstruction, defined as a progression of hydronephrosis or a 10% reduction in differential glomerular filtration rate on serial ultrasonography and diuretic renography (Koff and Campbell, 1994). All treated patients had a return of

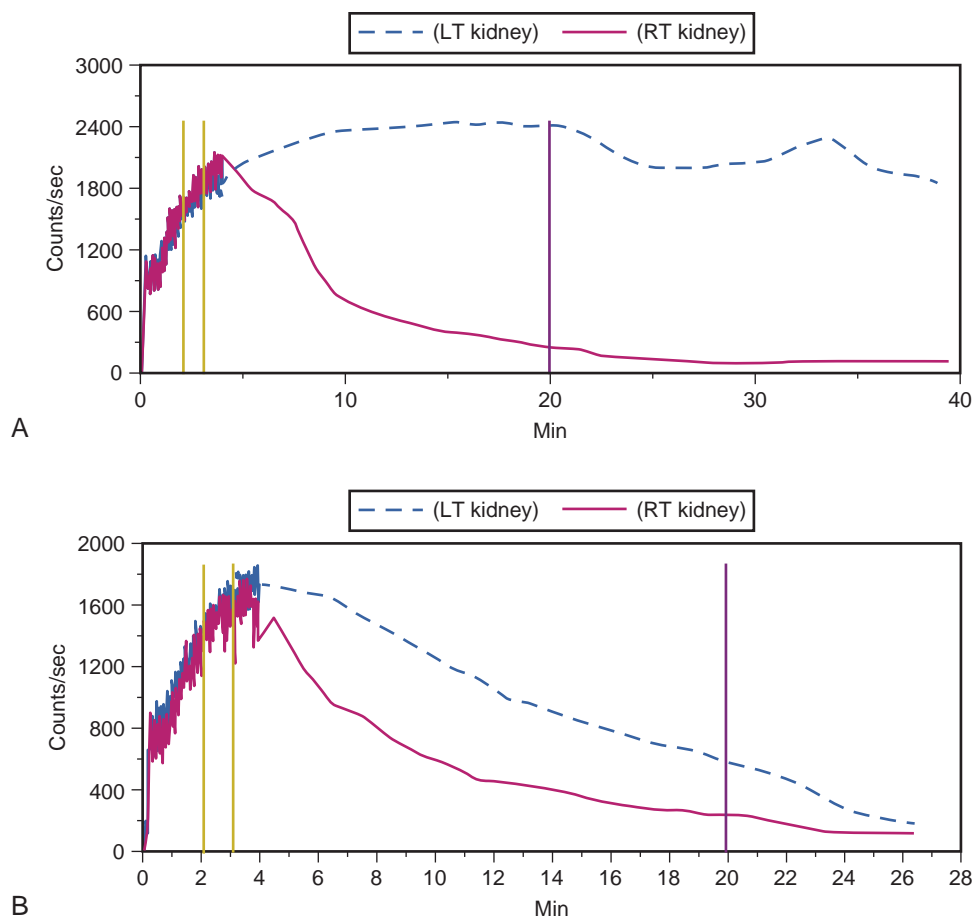

Figure 49-6. A, ^{99m}Tc -mercaptoacetyltri-glycine (MAG3) diuretic renography revealing functional ureteropelvic junction obstruction of the left kidney, with a $T_{1/2}$ greater than 40 minutes. Furosemide was administered 20 minutes into the study (vertical purple line). B, Follow-up study reveals normal renal drainage after robotic pyeloplasty with spontaneous drainage before furosemide administration.

renal function to predetermination levels, supporting selective nonoperative management of neonatal hydronephrosis.

UPJO may not become apparent until middle age or later (Jacobs et al, 1979). Occasionally, if the patient is asymptomatic and the physiologic significance of the obstruction seems indeterminate, careful observation with serial follow-up renal scans is appropriate. Gurbuz and colleagues observed minimally symptomatic UPJO and found 29% required surgery over a 4-year period (Gurbuz et al, 2011). Gulur and colleagues noted that 3 of 14 patients with UPJO lost less than 10% renal function over a mean of 44 months of observation (Gulur et al, 2009). However, the majority of affected patients ultimately benefit from reconstructive intervention (Jacobs et al, 1979; Clark and Malek, 1987; O'Reilly, 1989). When intervention is indicated, the procedure of choice has historically been dismembered pyeloplasty; however, less invasive endourologic approaches have a role as an alternative (Brannen et al, 1988; Motola et al, 1993a; Kletscher et al, 1995; Cohen et al, 1996; Nadler et al, 1996; Thomas et al, 1996; Tawfik et al, 1998; Lechevallier et al, 1999; Gerber and Kim, 2000; Nakada, 2000; Conlin, 2002). Moreover, laparoscopic and robotic pyeloplasty has gained acceptance as primary therapy at centers with appropriate experience (DiMarco et al, 2006; Rassweiler et al, 2007).

Although success rates with most endourologic techniques have not proven to be comparable with those of pyeloplasty, it has been suggested that the success rates may be improved with careful patient selection. In an important prospective study, Van Cangh and colleagues (1994) achieved an overall success rate for endopyelotomy of 73%. However, these investigators found the presence of

crossing vessels to be a major determinant of outcome (42% success rate in the setting of a crossing vessel vs. 86% success without a crossing vessel). Furthermore, when endopyelotomy was applied to patients with "a high degree of obstruction," the success rate was only 60% compared with an 81% success rate for those patients with "low-grade" obstruction. When patients with both a crossing vessel and a high degree of obstruction were excluded from analysis, the success rate improved to 95%, which is comparable with that of open pyeloplasty. However, other studies have suggested a less important role for these factors with regard to their impact on a successful outcome (Gupta et al, 1997; Danuser et al, 1998; Nakada et al, 1998). The use of color Doppler imaging has proven effective in diagnosing crossing vessels, as have magnetic resonance imaging (MRI) and CT (Mitterberger et al, 2008). Moreover, an incisional approach may be favored in patients who are poor surgical candidates or in patients poorly suited to an abdominal approach (Elabd et al, 2009).

Although the indications for intervention for UPJO are similar regardless of technique, it is critical to discuss the risks and benefits of all available options with patients. Accordingly, each patient should be advised individually on the basis of all the anatomic and functional information available preoperatively. In this setting, many patients will opt for a minimally invasive approach, even with the understanding that success rates may be lower or that secondary intervention may become necessary. As a result of studies linking crossing vessels to hindered endourologic successes, there is increased interest in intraoperative management of the UPJ and crossing vessel by either an open or a laparoscopic approach (Conlin, 2002). Therefore, for secondary UPJO, it remains

reasonable to recommend an open or laparoscopic approach to any patient in whom primary endourologic management has failed and an endourologic approach to those in whom open or laparoscopic repair has failed. Of note, the results of endourologic management after failed pyeloplasty remain excellent (Jabbour et al, 1998; Canes et al, 2008; Patel et al, 2011).

Rarely, nephrectomy may be the procedure of choice. Indications for nephrectomy as primary therapy include diminished function or nonfunction of the involved renal moiety and a normal contralateral kidney on the basis of radiographic and nuclear studies. These patients may be symptomatic with urinary tract infections or pain. In such cases, ultrasonography or CT scanning is typically performed and will reveal only a thin shell of parenchyma remaining. Renography can provide quantitative measures of renal function, and, in general, kidneys with less than 15% differential function are nonsalvageable in adults. If the potential for salvageability of function is still unclear, an internal stent or percutaneous nephrostomy may be placed for temporary relief of obstruction and renal function studies subsequently repeated. Nephrectomy may also be considered for patients in whom the obstruction has led to extensive stone disease with chronic infection and significant loss of function in the face of a normal contralateral kidney. Removal of the kidney may also be chosen over reconstruction for patients in whom repeated attempts at repair have already failed and in whom further intervention would therefore be extremely complicated. This option should be considered only when the contralateral kidney is essentially normal.

Options for Intervention

Endourologic Management. Operative intervention for UPJO has historically provided a widely patent, dependently positioned, well-funneled UPJ. In addition, the option to reduce the size of the renal pelvis is readily available with this approach. Although formal pyeloplasty has stood the test of time with a published success rate of nearly 95%, endourologic alternatives to standard operative reconstruction are still used (Clark et al, 1987; Elabd et al, 2009). The advantages of endourologic approaches include reduced hospital stays and postoperative recovery. However, the success rate does not approach that of open, laparoscopic, or robotic pyeloplasty. Furthermore, whereas open, laparoscopic, or robotic pyeloplasty can be applied to almost any anatomic variation of UPJO, consideration of any of the less invasive alternatives requires that the surgeon take into account the degree of hydronephrosis, ipsilateral renal function, concomitant calculi, and possibly the presence of crossing vessels. Of note, Albani and colleagues (2004) reported contemporary long-term results with various endopyelotomy approaches to have a success rate of 67%, with the majority of failures in the first 32 months. More recently, DiMarco and colleagues (2006) reported long-term follow-up of more than 400 patients undergoing either percutaneous antegrade endopyelotomy or pyeloplasty. The 3-, 5-, and 10-year success rates were superior for pyeloplasty, 85% versus 63%, 80% versus 55%, and 75% versus 41%. Moreover, Rassweiler and colleagues (2007) compared retrograde laser endopyelotomy with laparoscopic retroperitoneal pyeloplasty in 256 patients in a 10-year single-surgeon experience and found success rates were 73% for laser endopyelotomy compared with 94% for pyeloplasty.

Endourologic management of UPJO was introduced by Ramsay and colleagues in 1984 as a “percutaneous pyelolysis” and then popularized in the United States by Badlani and colleagues (1986), who coined the term *endopyelotomy*. Although various nuances in the technique have been described (Korth et al, 1988; Van Cangh et al, 1989; Ono et al, 1992), the basic concept of the endopyelotomy is a full-thickness lateral incision through the obstructing proximal ureter, from the ureteral lumen out to the peripelvic and periureteral fat. A stent is placed across the incision and is left to heal, in keeping with the original work of Davis in 1943, who performed an “intubated ureterotomy” to repair UPJO. Subsequently, alternative techniques using a retrograde approach to the UPJ were developed. The retrograde approach most used today is

the ureteroscopic approach, typically using the holmium laser to incise the UPJ under direct visual control. Alternatively, a cautery wire balloon endopyelotomy, which incises the UPJ under fluoroscopic control, or percutaneous endopyeloplasty may be used (Gill et al, 2002; Elabd et al, 2009). Recently, Vaarala and colleagues reported a small series of 64 patients who underwent either antegrade or retrograde cold knife or cautery wire balloon endopyelotomy. In this study, success rates ranged from 79% to 83%, without statistically significant differences among the three treatments (Vaarala et al, 2008). Of note, transplantation complications are particularly suited to endoscopic management, either antegrade or retrograde (Schumacher et al, 2006; Gdor et al, 2008b). As far as efficacy is concerned, there continues to be little evidence for significant differences among endopyelotomy techniques. The differences lie in technical considerations and complications.

Percutaneous Antegrade Endopyelotomy

Indications and Contraindications. The indications to intervene for any patient with UPJO include the presence of symptoms, progressive or overall impairment of renal function, development of upper tract stones or infection, or, rarely, causal hypertension. Historically, a percutaneous approach for definitive management of UPJO was offered only to those patients undergoing percutaneous removal of associated stones or to those in whom open pyeloplasty had previously failed. However, encouraging results ultimately led many centers to offer percutaneous endopyelotomy as primary therapy for almost any patient with UPJO. Even with the acceptance of laparoscopic and robotic pyeloplasty, percutaneous endopyelotomy remains appropriate for patients with UPJO and concomitant pyelocalyceal stones, which can then be managed simultaneously. Contraindications to a percutaneous endopyelotomy are similar to the contraindications to any endourologic approach and include a long segment (>2 cm) of obstruction, active infection, and untreated coagulopathy. Whereas the impact of crossing vessels is controversial, the mere presence of crossing vessels is not a contraindication to an endopyelotomy (Motola et al, 1993b; Nakada et al, 1998; Lam et al, 2003b). However, significant entanglement of the UPJ by crossing vessels can occasionally be identified, and this may render any endourologic approach unsuccessful. When such entanglement is suggested by intravenous or retrograde pyelography, it can be reliably verified with 3D helical CT (Kumon et al, 1997) (Fig. 49-7).

Figure 49-7. A, Contrast-enhanced computed tomography scan reveals apparent right ureteropelvic junction obstruction in this patient with right flank pain. A crossing lower pole artery is visible on this coronal section.

Patient Preparation. Patients undergoing a percutaneous endopyelotomy undergo preoperative evaluation and preparation as if they were undergoing any percutaneous, laparoscopic, or open renal intervention. The evaluation includes an assessment for any comorbidity that may increase the risk of anesthesia. Sterile urine should be ensured at the time of definitive intervention. If upper tract infection cannot be cleared because of obstruction, temporization should be accomplished through use of internal stenting or percutaneous nephrostomy drainage alone. The patient should be counseled as to the risks and benefits of the procedure, and in particular the fact that the success rate of any endourologic approach, including percutaneous endopyelotomy, may be less than that of formal reconstruction. Patients should also be counseled of the risk of bleeding requiring transfusion, urinary leak, drainage-related complications, and hydropneumothorax, particularly if upper pole access is used.

Technique. An endopyelotomy cannot be performed safely by any route until access across the UPJ is established. This can be accomplished in a retrograde fashion cystoscopically or in an antegrade manner percutaneously. For retrograde access, the UPJ can almost always be traversed using a hydrophilic wire passed through an open-end catheter. Once the hydrophilic wire is successfully positioned in the pyelocalyceal system, the open-end catheter is advanced over it into the renal pelvis. The wire can then be withdrawn so that contrast material can be injected through the open-end catheter to guide subsequent percutaneous access.

With the patient in the prone position, the site for percutaneous access is chosen to allow straightforward access to the UPJ. In general, a midposterior or superolateral calyx is chosen, although occasionally an inferolateral calyx may be used. Typically, the UPJ can be intubated in an antegrade fashion when the tract is initially established with fluoroscopic control. Alternatively, once the tract has been dilated and nephroscopy has been performed, a wire can again be passed in a retrograde fashion through the open-end catheter and grasped from above so that through-and-through access is reestablished. In either case, as soon as access is obtained with one wire, an introducing catheter is used to pass a second wire as a safety wire, so a working and a safety wire are now both in place. At this point, percutaneous access is complete and the endopyelotomy may be performed.

In the original descriptions of the technique both from the Institute of Urology in London (Ramsay et al, 1984) and from Long Island Jewish Hospital in New York (Badlani et al, 1986),

the endopyelotomy was performed using a cold knife technique under direct vision. With one or two wires in place across the UPJ, a direct vision “endopyelotome” is used. This hook-shaped cold knife may be used to completely incise the UPJ in a full-thickness manner, from the ureteral lumen to periureteral and peripelvic fat. **Rigorous anatomic studies have shown the incision should usually be made laterally because this is the location devoid of crossing vessels** (Sampaio and Favorito, 1993; Sampaio, 1998). However, in cases of high insertion, the incision should instead “marsupialize” the proximal ureter into the renal pelvis, such that an anterior or posterior incision may be required. When such incisions are done under direct vision, any crossing vessel can be directly visualized and avoided. In addition to the endopyelotome, the holmium laser or the cutting balloon catheter may also be used to perform an antegrade endopyelotomy.

Once the incision is complete, stenting is accomplished. There remains no consensus as to the optimal stent size or duration for endopyelotomy. A No. 14/7-Fr endopyelotomy stent may be used, passed in an antegrade fashion with the larger-diameter end of the stent positioned across the UPJ. In some cases, especially when the patient has not been pre-stented, passage of this large-caliber stent may be difficult. In those instances, a No. 10/7-Fr endopyelotomy stent or even a standard No. 8-Fr internal stent may be used without compromising the ultimate outcome. Once proper positioning of the stent has been determined fluoroscopically, any remaining safety wires are withdrawn. One group showed no difference between larger and standard stents in a porcine study of endopyelotomies (Moon et al, 1995). Alternatively, Danuser and colleagues (2001) demonstrated improved success rates using a modified 27-Fr stent after percutaneous endopyelotomy at nearly 2 years of follow-up.

In the setting of a high insertion, the incision can often be extended to the dependent portion of the renal pelvis under direct vision, bridging the gap between the lateral wall of the ureter and the medial wall of the pelvis, across the periureteral and peripelvic fat (Fig. 49-8). Once the incision is complete, the stent is already in place and nephrostomy drainage is instituted for 24 to 48 hours.

Postoperative Care. Avoidance of strenuous activity for 8 to 10 days after the procedure is recommended. The ideal stent size, duration of stent placement, and radiographic follow-up after endopyelotomy remain unclear (Canes et al, 2008). One study did report a benefit to larger stents in patients undergoing antegrade endopyelotomy (71% vs. 93%); however, a large-bore (27-Fr) catheter was

Figure 49-8. A, Retrograde study in this patient with left ureteropelvic junction obstruction reveals a “high insertion” of the left ureter. B, Computed tomography scan in the same patient reveals the ureter inserting on the anatomically anterior aspect of the renal pelvis. A marsupializing incision must be made in a true posterior direction from the ureter into the renal pelvis.

used for the initial 3 weeks postoperatively (Danuser et al, 2001). On the other hand, Kletscher and colleagues (1995) reported no benefit to larger stents, as did Hwang and colleagues (1996). Wolf and colleagues (1997) reported improved success using larger stents (12 Fr) in endouretotomy patients in a retrospective review. Regarding stent duration, less is known. The original report and recommendation of 6 weeks by Davis (1943) is still often used, although Mandhani and colleagues (2003) identified no difference in results when comparing 57 patients stented for 2 weeks versus 4 weeks. Although the need for prophylactic antibiotics while the stent is indwelling is not literature based, many use a daily suppressive dose.

Once the stent is removed, the patient returns 1 month later for clinical follow-up and radiographic evaluation. In general, this includes a history, physical examination, urinalysis, and diuretic renography. If the patient remains asymptomatic and the diuretic renography reveals normal drainage (normal $T_{1/2}$), reevaluation is performed at 6 months and then at 12-month intervals. Most literature indicates that the majority of endopyelotomy failures occur within the first year of the procedure; however, longer-term studies demonstrate failures well beyond that timeframe (Nadler et al, 1996; Albani et al, 2004; DiMarco et al, 2006; Doo et al, 2007). For most adults, 2- to 3-year follow-up is justified because studies indicate that even at 36 months some late failures are identified, but relatively few are identified at 60 months (Doo et al, 2007).

Results. The immediate and long-term results of percutaneous endopyelotomy are well established. Although percutaneous endopyelotomy compares favorably with open operative pyeloplasty in terms of postoperative pain, length of hospital stay, and return to prehospitalization activities (Karlin et al, 1988; Brooks et al, 1995), retrograde endopyelotomy and laparoscopic and robotic pyeloplasty also offer favorable convalescence.

Gerber and Lyon in 1994 reviewed the outcome of percutaneous endopyelotomy in 672 patients reported from 12 centers and found a success rate ranging from 57% to 100% (mean, 73.5%) at follow-up ranging from 2 to 96 months. Currently, success rates approaching 85% to 90% are being reported at experienced centers, with little difference in outcome noted in those patients undergoing the procedure for primary versus secondary UPJO (Motola et al, 1993a; Kletscher et al, 1995; Shalhav et al, 1998). Of note, Knudsen and colleagues (2004) reported long-term results in 80 patients after use of the cold knife and holmium laser for antegrade endopyelotomy, with 55-month follow-up. This series had a success rate of 67%, slightly lower than otherwise reported. It is interesting to note that DiMarco and colleagues (2006) reported on 182 antegrade endopyelotomies with a recurrence-free survival over 10 years at a single center as low as 41%. Of note, Schumacher and colleagues (2006) reported on three successful antegrade endopyelotomies in transplanted kidneys in 2006.

When percutaneous endopyelotomy does fail, several options exist including a retrograde endopyelotomy; repeat percutaneous endopyelotomy; and laparoscopic, robotic, or open operative intervention. There remains a role for spiral CT angiography in failed endopyelotomy, to rule out a crossing vessel. If a significant vessel is found, repeat endopyelotomy is usually not recommended (Nakada et al, 1998; Sampaio, 1998; Nakada, 2000). Alternatively, operative intervention is typically offered to any patient in whom an endourologic approach has failed. Some studies suggest that the results of laparoscopic pyeloplasty will not be compromised, whereas Sundaram and colleagues reported longer operative times in these circumstances (Motola et al, 1993b; Gupta et al, 1997; Conlin, 2002; Sundaram et al, 2003).

Complications. The complications associated with percutaneous endopyelotomy are analogous to those associated with percutaneous nephrolithotomy (Badlani et al, 1988; Weiss et al, 1988; Cassis et al, 1991; Malden et al, 1992; Bellman, 1996), and hemorrhage is a risk of any percutaneous upper tract procedure including endopyelotomy. However, because in patients with UPJO the renal parenchyma is usually thinner than that associated with a normal kidney, and because the collecting system is dilated, this risk may be different than that in the general population of stone

patients undergoing percutaneous manipulation. Acute management in this setting is usually conservative to start: bed rest, hydration, and transfusion if necessary. The nephrostomy tube should not be irrigated acutely. Rather, it is preferable to allow the pyelocoliceal system to tamponade the bleeding. When continued bleeding does not respond to these conservative measures, the next step is selective angiographic embolization. **In general, the urologist should have a low threshold to proceeding to angiography, to minimize the need for transfusion and potential exploration. Successful angiographic embolization often obviates the need for operative intervention.**

Infection is a risk of any urinary tract manipulation including percutaneous endopyelotomy, and all attempts should be made to sterilize the urinary tract before the procedure. Whereas the role of prophylactic antibiotics at the outset of the procedure in the setting of a sterile urine is unproven, most urologists give a second-generation cephalosporin "on call" to the procedure. Consideration should be given to the use of prophylactic antibiotics while the endopyelotomy stent is indwelling for the month after the procedure, especially in women who are more prone to bacteriuria.

Persistent obstruction is rare in the early postoperative period because of the internal stent. Occasionally the stent can be obstructed from blood clots, and continued nephrostomy drainage for a few days typically allows the problem to resolve spontaneously.

Percutaneous Endopyeloplasty. Percutaneous endopyeloplasty is a hybrid technique described as an endoscopic Heineke-Mikulicz repair performed through a percutaneous tract. In other words, endopyeloplasty combines percutaneous endopyelotomy and an endoscopic Fenger plasty. Stein and colleagues reported 55 patients with short-term follow-up with more than 90% success (Stein et al, 2007). Endopyeloplasty may not be effective for secondary UPJO because tissue scarring may inhibit the endoscopic reconstruction. More recently a technique modification was reported requiring no specialized equipment (laparoscopic needle holders and a nephroscope) in 10 patients (Lezrek et al, 2012). Regardless, this procedure is less mainstream at this time.

Simultaneous Percutaneous Endopyelotomy and Nephrolithotomy. Percutaneous endopyelotomy is appropriate when the UPJO is associated with upper tract stone disease because the stones can be managed concomitantly. In such cases, percutaneous access is again established with a wire across the UPJ. The stone should be removed before the endopyelotomy so that stone fragments do not migrate into the peripelouretal tissue, as can happen if the endopyelotomy is performed first. Otherwise, localized obstruction may result from fibrosis or granuloma formation (Giddens et al, 2000; Streem, 2000). The urologist must take care to ensure that the UPJO is not a result of edema from the concomitant stone disease, in particular with stone disease in the renal pelvis. In this circumstance, initial management of the stone percutaneously and subsequent radiographic assessment of the UPJ once the stone has been removed are most prudent. In addition, if a nephrostomy tube is retained, a Whitaker test is straightforward and definitive to assess for persistent obstruction. Conversely, UPJO and solitary lower pole calculi do not represent a dilemma regarding UPJ edema, and combined percutaneous management remains most efficient. Alternatively, laparoscopic or robotic pyeloplasty with concomitant stone removal is also effective for these patients. Often the deciding factor between percutaneous and laparoscopic approaches relates to the stone burden present and the experience of the surgeon (Sutherland and Jarrett, 2009).

Retrograde Ureteroscopic Endopyelotomy. A ureteroscopic approach to endopyelotomy was first suggested in 1985 when Bagley and colleagues reported a combined percutaneous and flexible ureteroscopic procedure approach for management of an "obliterated" UPJ (Bagley et al, 1985). Subsequently, Inglis and Tolley (1986) reported a ureteroscopic "pyelolysis" for UPJO. Shortly thereafter, Clayman and colleagues (1990) reported an initial experience in a small number of patients with ureteroscopic endopyelotomy with a 3-Fr or 5-Fr cutting electrode passed under direct vision using large, rigid or flexible ureteroscopes. In that series, however, an 8-Fr nephrostomy tube was placed at the outset

of the procedure and left indwelling for at least 48 hours. Therefore, that series still represented a “combined” endourologic approach to endopyelotomy. Stents were routinely left in place for 6 to 8 weeks, after which diagnostic studies were performed. With a mean follow-up approaching 1 year, a success rate of 81% was achieved in 16 patients. However, two patients developed distal ureteral strictures, probably resulting from the larger-diameter rigid instrumentation. Cold knife ureteroscopic endopyelotomies are still reported. [Butani and Eschghi \(2008\)](#) identified 96% success rates in primary procedures with an average 5-year follow-up, although rigid ureteroscopy and preprocedure stents were necessary.

Advances in instrumentation and technique now allow a ureteroscopic approach to be performed reliably at a single setting ([Conlin and Bagley, 1998](#)), and this is now considered the standard. The main advantage of a ureteroscopic approach is that it allows direct visualization of the UPJ and assurance of a properly situated, full-thickness endopyelotomy incision without the need for percutaneous access. Another advantage of the ureteroscopic approach is a decrease in cost compared with the use of the cautery wire balloon, assuming ureteroscopic equipment and electroincision or holmium laser are already available. Moreover, the risks and morbidity of percutaneous access are avoided with the ureteroscopic procedure. [Gettman and colleagues](#) found that the retrograde ureteroscopic endopyelotomy was more cost effective than hot-wire cutting balloon endopyelotomy, antegrade endopyelotomy, and pyeloplasty for treating UPJO when taking into account treatment failures ([Gettman et al, 2003](#)).

Indications and Contraindications. The indications for a ureteroscopic endopyelotomy include functionally significant obstruction, as defined earlier. Contraindications include long areas of obstruction and upper tract stones, which are best managed simultaneously with alternative approaches, usually percutaneously or laparoscopically. Another consideration is that in patients with significant hydronephrosis, the evidence indicates an antegrade endopyelotomy may be more efficacious ([Lam et al, 2003b](#)).

Technique. The instrument that allows the most straightforward retrograde access to the UPJ, as well as providing an effective working channel, is a small caliber (≤ 7 -Fr) semirigid ureteroscope. In women, the UPJ can often be reached with a 6.9-Fr semirigid ureteroscope. In men, small-caliber (≤ 7.5 -Fr) actively deflecting flexible ureteroscopes are typically used, and today with availability of improved ureteral access sheaths and improved flexible ureteroscopes, many retrograde endopyelotomies are done using the flexible ureteroscope.

General anesthesia is used to minimize patient movement during ureteroscopy and the subsequent incision of the UPJ. In preparation for the endopyelotomy, a retrograde pyelogram is performed under fluoroscopic control at the outset of the procedure. A hydrophilic guidewire is passed cystoscopically under fluoroscopic control and coiled in the pyelocalyceal system. The cystoscope is then withdrawn and exchanged for the semirigid ureteroscope. The ureteroscope is passed alongside the guidewire to the level of the UPJ. If the distal ureter is too narrow to allow easy passage of the ureteroscope, the intramural ureter can be dilated using a 5-mm balloon or a 9- or 10-Fr “introducing” catheter. If the ureter is still too narrow at any point to easily accommodate the ureteroscope, then an internal stent is placed and the procedure postponed for 5 to 10 days to allow passive ureteral dilation. Alternatively, an actively deflecting flexible ureteroscope may be used, and in most cases a ureteral access sheath is quite useful. The sheath allows for rapid transfer of the ureteroscope for assessment of the UPJ. Once the flexible ureteroscope is passed to the UPJ, a 200- μ m holmium fiber is placed through the working channel and the UPJ is incised in the appropriate location, as suggested by the radiographic studies ([Figs. 49-9 and 49-10](#)).

Once the UPJ is reached with the ureteroscope, the renal pelvis is drained to assist movement across the UPJ during the incision. When using a semirigid ureteroscope, the 200- or 365- μ m holmium laser fiber is inserted through the working channel as the ureteroscope is positioned at the proximal extent of the UPJ or in the renal

pelvis itself. At a setting of 0.8 to 1.2 J and a frequency of 10 to 15 Hz, the UPJ is incised, usually in a posterolateral direction, while the ureteroscope is withdrawn back down across the UPJ. This procedure is repeated, and the incision gradually deepened to extend into the peripelvic and periureteral retroperitoneal space. Because this is done gradually and under direct vision, any visualized vessels, and thus potentially significant bleeding, are usually avoided.

The incision is carried caudally into normal ureteral tissue, until the UPJ is widely patent. Injection of contrast material through the ureteroscope can demonstrate extravasation and confirm an adequate depth of incision, although this is usually not necessary because the entire procedure has been performed under direct vision. Balloon dilation up to 24 Fr can also be performed to complete the incision. If any small bleeding points are visualized ureteroscopically, they can be treated by defocusing the holmium laser. Similarly, the balloon can be reinflated to allow tamponade for 10 minutes to see if the bleeding will subside. The ureteroscope is then withdrawn from the ureter while the safety wire is left in place in the renal pelvis for subsequent passage of a stent. Experimental studies have shown that 36-Fr balloon dilation alone can create linear incisions in the UPJ ([Pearle et al, 1994](#)). Although retrograde balloon dilation alone has been reported for treatment of UPJO, long-term follow-up studies have shown a diminishing success rate over time, as low as 42% ([McClinton et al, 1993; Webber et al, 1997](#)).

Once the ureteroscope has been removed, a stent is advanced over the remaining wire using fluoroscopic guidance. A Foley catheter is left indwelling, again to obviate the risk of reflux and extravasation at the site of the endopyelotomy incision and to rapidly identify any significant bleeding. Diuretic renography is performed 4 weeks after stent removal to assess results. Clinical and radiographic follow-up is then continued at 6- to 12-month intervals for 24 to 32 months.

Results. [Biyani and colleagues \(1997\)](#) described their initial experience with a ureteroscopic approach using holmium laser energy. With a mean follow-up of slightly more than 12 months, they achieved a success rate of 87.5% in a small group of patients. One patient developed a urinoma, which was managed conservatively. In 1998, [Renner and colleagues](#) reported a larger series of patients undergoing ureteroscopic laser endopyelotomy. With a semirigid ureteroscope, the UPJ was incised at a posterolateral location unless vessels were visualized in that area, in which case a contralateral incision was made. [Tawfik and colleagues \(1998\)](#) reported the Jefferson Medical College experience with ureteroscopic endopyelotomy. These investigators combined endoluminal ultrasound with their ureteroscopic approach to definitively identify crossing vessels or a ureteropelvic septum, which is present in patients with high-inserting ureters. The authors believed this helped them definitively site their endopyelotomy incision. Different modalities were used for the endopyelotomy itself including electrocautery and holmium laser. An 87.5% success rate was achieved in 32 patients. There were no significant bleeding complications, and all patients were discharged within 24 hours of the procedure.

Several investigators have reported success rates of 70% to 80% with follow-up out to 5 years using ureteroscopic holmium laser endopyelotomy ([Gerber and Kim, 2000; Matin et al, 2003; Elabd et al, 2009](#)). [Yanke](#) reported on 128 retrograde ureteroscopic endopyelotomies with a 60% success rate at 20 months; [Rassweiler and colleagues](#) reported 73% success in 113 patients at 63 months ([Rassweiler et al, 2007; Yanke et al, 2008](#)). Improved results were reported by [Conlin](#) (91% success rates) with retrograde endopyelotomy in patients when culling patients with crossing vessels greater than 4 mm using preoperative ultrasonography ([Conlin, 2002](#)). [Giddens and colleagues](#) also published excellent results after culling patients with anterior and posterior crossing vessels from retrograde endopyelotomy using endoluminal ultrasound ([Giddens et al, 2000](#)). Today, endoluminal ultrasound is rarely used to identify crossing vessels because similar data can be obtained using less invasive studies ([Mitterberger et al, 2008](#)). Regardless, the best endopyelotomy success rates still lag behind those of open or laparoscopic pyeloplasty.

Figure 49-9. Flexible ureteroscopic endopyelotomy using holmium laser, demonstrating endoscopic view of the ureteropelvic junction (*inset*). A safety wire is in place, and the ureterscope is passed through a ureteral access sheath as a lateral incision is being made under endoscopic view, using holmium laser fiber. A properly sited, complete incision is straightforward with this direct visualization technique.

Complications. Complications of this approach have diminished in frequency and severity with the refinement of ureteroscopic instrumentation and the introduction of small-caliber holmium laser fibers. Postprocedural ureteral strictures are rare in contemporary series, and angiographic embolization and nephrectomy are rare when the retrograde approach is used. Most complications are minor and relate primarily to urinary leak, stent migration, and infection (Tawfik et al, 1998; Gerber and Kim, 2000). Castle and colleagues reported on ureteroarterial fistula 2 weeks

after retrograde laser endopyelotomy, which could be fulgurated ureteroscopically (Castle et al, 2009).

Retrograde Cautery Wire Balloon Endopyelotomy. Use of a cautery wire balloon for management of UPJO was first reported in a clinical series by Chandhoke and colleagues in 1993. Because the procedure is guided fluoroscopically, such vessels may increase the risk of hemorrhage after activation of the cautery wire balloon (Wagner et al, 1996). Some authors recommended preoperative imaging for such vessels with relatively noninvasive techniques such

Figure 49-10. A, Endoscopic view of ureteropelvic junction (UPJ) stenosis with safety wire and laser fiber during incision. B, After incision, note full-thickness incision and minimal bleeding with capacious UPJ.

as CT or 3D CT angiography (Stroom and Geisinger, 1995; Quillin et al, 1996; Nakada et al, 1998; Herts et al, 1999; Nakada, 2000). Nadler and colleagues (1996) reported on 28 patients 2 or more years after cautery wire balloon endopyelotomy. With a mean follow-up of 32.5 months, subjective improvement was noted in 61% of patients, and 81% had a patent UPJ on the basis of diuretic renography or Whitaker testing. More recent studies have demonstrated lower success rates than these initial series (32% to 63%) and perhaps that high-grade hydronephrosis has a negative impact on success (Albani et al, 2004; Sofras et al, 2004). El-Nahas and colleagues (2006) reported a small prospective randomized trial comparing retrograde ureteroscopic endopyelotomy to the hot-wire balloon endopyelotomy in 40 patients. Although the results were not statistically significant, they found superior success rates (85% compared with 65%) and lower complication rates with the ureteroscopic endopyelotomy. Ponsky and Stroom (2006) reported on 64 patients undergoing either ureteroscopic endopyelotomy or hot-wire balloon endopyelotomy and found equivalent success rates with both procedures yet higher major complication rates in the cautery wire balloon endopyelotomy, specifically transfusion and selective embolization. Elabd and colleagues (2009) reported a higher rate of hemorrhage using this technique compared with a laser incisional approach. In summary, improved ureteroscopic instrumentation, laser technology, and the benefits of direct endoscopic visualization make ureteroscopic endopyelotomy the pervasive retrograde approach.

Operative Interventions

Historical Notes. The historical aspects of UPJ repair were previously examined by Kay (1989) and by Schaeffer and Grayhack (1986). The first reconstructive procedure was performed by Trendelenburg in 1886; however, the patient died of postoperative complications. In 1891 Kuster divided the ureter and reanastomosed it to the renal pelvis, thus apparently performing the first successful dismembered pyeloplasty (Kuster, 1892). Kuster's technique, however, was prone to recurrent stricture. In 1892 Fenzer applied the Heineke-Mikulicz principle to UPJ repair. This surgical technique involves transverse closure of a longitudinal incision. However, this technique can cause shortening of the suture line on one side, thus resulting in buckling or kinking of the UPJ with recurrent obstruction. In 1916 Schwyzer introduced the Y-V pyeloplasty, which was subsequently modified by Foley in 1937 (Foley, 1937). However, this technique was best applied to high ureteral insertions and was essentially unsuitable when the UPJ itself was already in a dependent position. Later, flap techniques were

KEY POINTS: ENDOUROLOGIC MANAGEMENT OF URETEROPELVIC JUNCTION OBSTRUCTION

- Contemporary indications for intervention for UPJO include the presence of symptoms associated with the obstruction, impairment of overall renal function or progressive impairment of ipsilateral function, development of stones or infection, or, rarely, causal hypertension.
- The advantage of endoscopic management is the avoidance of the intra-abdominal approach; however, the success rates do not approach that of laparoscopic or robotic pyeloplasty.
- Whereas open, laparoscopic, or robotic operative intervention can be applied to almost any anatomic variation of UPJO, consideration of any of the less invasive alternatives requires that the surgeon take into account the degree of hydronephrosis, ipsilateral renal function, concomitant calculi, and, possibly, the presence of crossing vessels.
- In general, the urologist should have a low threshold to proceeding to angiography in patients with bleeding after endopyelotomy to minimize the need for transfusion and potential exploration. Successful angiographic embolization often obviates the need for operative exploration, which can lead to nephrectomy.

developed that were more universally applicable including the spiral flap of Culp and DeWeerd (1951) and the vertical flap of Scardino and Prince (1953). Thompson and colleagues (1969) reported the use of a renal capsular flap for complex cases in which an adequate amount of renal pelvis is not available for repair.

In 1949 Nesbit followed the principle of Kuster's dismembered procedure and further modified it by creating an elliptical anastomosis to decrease the likelihood of stricture formation at the site of repair. Also in 1949, Anderson and Hynes described their modifications of this dismembered technique that involved anastomosis of the spatulated ureter to a projection of the lower aspect of the pelvis after a redundant portion was excised (Anderson and Hynes, 1949). Use of healing by secondary intention was also investigated in the similar time period. The techniques of intubated ureterotomy were popularized by Davis in 1943, but they had been previously described by Fiori in 1905, Albarran in 1909, and Keyes in 1915.

Developments in minimally invasive surgery have led to a dramatic rise in the use of laparoscopic and robotic techniques in the reconstruction of the UPJ (Jacobs et al, 2013). Irrespective of

surgical approach, several basic principles must always be applied to maximize the success of surgical repair. **For any procedure, the resultant anastomosis should be widely patent and completed in a watertight fashion without tension. In addition, the reconstructed UPJ should allow a funnel-shaped transition between the pelvis and the ureter that is in a position of dependent drainage.** Because the goal of minimally invasive surgery is to mimic open surgery, the operative principles are reviewed here together with specific technical nuances for each approach.

Before the definitive surgical management, drainage of a kidney with UPJO is recommended only in select circumstances including infection associated with the obstruction or azotemia resulting from obstruction in a solitary kidney or bilateral disease. Procedural drainage may be of value in the uncommon scenario of severe, unrelenting pain requiring emergent relief of obstruction. For any of these situations, such drainage can be achieved by placement of an internal ureteral stent or a percutaneous nephrostomy tube. **The clinical indications for placement of stents or nephrostomy tubes intraoperatively remain controversial and vary among urologists.** For adults, our preference is for routine placement of a soft, inert, self-retaining internal ureteral stent, which is removed 4 to 6 weeks postoperatively. Such stents in adults can be easily removed in an outpatient office setting using local anesthesia. Routine use of internal ureteral stents offers several advantages, especially in the early postoperative period. Such practice appears to decrease the amount and length of time of urinary extravasation at the surgical repair site, thereby decreasing the risk of secondary fibrosis. Decreased urinary extravasation also allows earlier removal of external drains. For uncomplicated pyeloplasty in adult patients, there appears to be no advantage to using both a nephrostomy tube and a stent because this may result in a prolonged hospital stay and an increased incidence of infection (Wollin et al, 1989). Instead, nephrostomy tubes may be reserved for complicated procedures such as those required for secondary UPJO or those associated with active inflammation. However, if a percutaneous nephrostomy tube was placed preoperatively, it is usually left in place to allow proximal diversion and access for antegrade radiographic studies during the postoperative period.

Although the use of internal stents and nephrostomy tubes remains somewhat controversial, provision of external drainage from the site of surgical repair is absolutely necessary. Such external drainage may be achieved with a Penrose or closed suction drain placed near, but not on, the suture line and brought out through a separate stab incision. This practice helps to minimize the risk of urinoma formation leading to possible disruption of the suture line, scarring, or sepsis.

Dismembered Pyeloplasty

Indications. At present, a dismembered pyeloplasty is preferred by most urologists in the surgical repair of UPJO because this procedure is almost universally applicable to the different clinical scenarios. This approach can be used regardless of whether the ureteral insertion is high on the pelvis or already dependent. It also permits reduction of a redundant pelvis or straightening of a tortuous proximal ureter. Furthermore, **anterior or posterior transposition of the UPJ can be achieved when the obstruction is the result of accessory or aberrant lower pole vessels (Boylu et al, 2009).** In addition, unlike the flap techniques, **only a dismembered pyeloplasty allows complete excision of the anatomically or functionally abnormal UPJ itself.** It is important to note that a dismembered pyeloplasty is not well suited to UPJO associated with lengthy or multiple proximal ureteral strictures or to patients in whom the UPJO is associated with a small, relatively inaccessible intrarenal pelvis. This surgical repair can be accomplished by either open or minimally invasive techniques, with the reconstruction of the UPJ being essentially the same.

Technique. Surgical exposure to the UPJ is achieved by first identifying the proximal ureter in the retroperitoneum. The proximal ureter is then dissected cephalad to the renal pelvis, leaving a large amount of periureteral tissue to preserve the ureteral blood supply. A marking stitch of fine suture can be placed on the lateral aspect of the proximal ureter, below the level of the obstruction, to assist

proper orientation for the subsequent repair. The UPJ tissue is typically excised, and the proximal ureter is then spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the proximal ureter is brought to the inferior border of the renal pelvis, and the medial side of the ureter is brought to the superior aspect (Fig. 49-11B). The anastomosis is then performed with fine interrupted or running absorbable sutures, placed full thickness through the ureteral and renal pelvic walls, in a watertight manner (Fig. 49-11C). As discussed earlier, our preference for adult patients is to routinely perform the anastomosis over an internal ureteral stent, which is left indwelling.

If the renal pelvis is exceptionally redundant, a “reduction” pyeloplasty can be performed by excising the redundant portion of the pelvis, but this is often unnecessary (Stein et al, 1996; Morsi et al, 2013) (Fig. 49-12). The cephalad aspect of the pelvis is then closed with running absorbable sutures down to the dependent portion, which will subsequently be anastomosed to the ureter. In the event that aberrant or accessory lower pole vessels are found in association with the UPJO, a dismembered pyeloplasty allows transposition of the UPJ in relation to these vessels (Fig. 49-13).

Surgical Approaches for Pyeloplasty

Open Surgery. Several types of open surgical incisions have been used for pyeloplasty in the management of UPJO. An anterior extraperitoneal approach is chosen by some because it allows surgical repair with minimal mobilization of the pelvis and proximal ureter. Alternatively, a posterior lumbotomy provides direct exposure to the UPJ and again allows repair with minimal mobilization of the surrounding structures. Like the anterior extraperitoneal approach, posterior lumbotomy is best suited to relatively thin patients without previous ipsilateral surgery. Our personal preference for most patients undergoing primary surgical repair of UPJO is an extraperitoneal flank approach. This incision may be subcostal but is usually performed through the bed of the 12th rib or carried anteriorly off its tip. The extraperitoneal flank approach is advantageous in that it is familiar to all urologists and provides excellent exposure without regard to body habitus. In the presence of other renal anomalies associated with the UPJ, such as horseshoe or pelvic kidney, anterior extraperitoneal approaches are often preferable, although laparoscopic management may be considered in this setting.

Laparoscopic and Robotic Intervention. Laparoscopic approach to pyeloplasty was first introduced in 1993 by Schuessler and colleagues (1993) and has been developed worldwide as a viable minimally invasive alternative to open pyeloplasty and endopyelotomy. Relative to both open pyeloplasty and endopyelotomy, laparoscopic pyeloplasty is associated with greater technical complexity and a steeper learning curve (Calvert et al, 2008). **In the hands of experienced laparoscopic surgeons, it has been shown to provide lower patient morbidity, shorter hospitalization, and faster convalescence, with the reported success rates matching those of open pyeloplasty (≥90%).** Autorino and colleagues conducted a meta-analysis of studies comparing open and minimally invasive pyeloplasty techniques and found both to have similar success and complication rates with a weighted mean difference in hospital stay of 2.68 days favoring minimally invasive surgery (Autorino et al, 2014). Following the similar surgical principles of anatomic dissection and repair used in open pyeloplasty, laparoscopic pyeloplasty has been shown to provide the success rates surpassing those of endopyelotomy by approximately 10% to 30% (Simforoosh et al, 2004).

The introduction of the surgical robotic platform, with its shorter learning curve and wristed instrumentation that facilitates the ergonomics of intracorporeal suturing, has led to widespread use of minimally invasive pyeloplasty. Gettman and colleagues reported the first patient experience with robotic-assisted laparoscopic pyeloplasty in 2002 (Gettman et al, 2002). Jacobs and colleagues (2013) reported a 360% increase in the use of minimally invasive pyeloplasty between 2001 and 2009, an increase that was felt to be at least in part related to adoption of robotic pyeloplasty at many

Figure 49-11. A, Traction sutures are placed on the medial and lateral aspects of the dependent portion of the renal pelvis in preparation for dismembered pyeloplasty. A traction suture is also placed on the lateral aspect of the proximal ureter, below the level of obstruction. This will help maintain proper orientation for the subsequent repair. B, Ureteropelvic junction is excised. The proximal ureter is spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the ureter is then brought to the inferior border of the pelvis while the medial side of the ureter is brought to the superior edge of the pelvis. C, Anastomosis is then performed with fine interrupted or running absorbable sutures placed full thickness through the ureteral and renal pelvis walls in a watertight fashion. In general, we prefer to leave an indwelling internal stent for adult patients. The stent is removed 4 to 6 weeks later.

Figure 49-12. A, For large or redundant renal pelvises, a reduction pyeloplasty is performed by excising the redundant portion between traction sutures. B, The cephalad aspect of the pelvis is then closed with running absorbable suture down to the dependent portion. C, The dependent aspect of the pelvis is then anastomosed to the proximal ureter.

Figure 49-13. When aberrant or accessory lower pole vessels are found in association with the ureteropelvic junction (UPJ) obstruction, a dismembered pyeloplasty allows transposition of the UPJ in relation to the vessels.

centers. Similarly, [Sukumar and coauthors \(2012\)](#) found that the use of minimally invasive pyeloplasty in the United States increased from 2.4% to 55.3% from 1998 to 2009, driven by robotics, which accounted for 45.1% of pyeloplasties performed in 2009. Preoperative, intraoperative, and postoperative techniques are analogous in these approaches, and therefore the next section refers to both laparoscopic and robotic pyeloplasty.

Indications and Contraindications. The indications and contraindications for a laparoscopic repair are similar to those for either an endourologic or an open operative procedure. Indications to intervene include the presence of clinical symptoms of UPJO, the progressive impairment of renal function, and the development of ipsilateral upper tract calculi or infection. Cases requiring the transposition of crossing vessels obstructing the UPJ or the size reduction for massively dilated renal pelvis are suitable for the laparoscopic approach. Absolute contraindications to intervention include the presence of uncorrected coagulopathy, the absence of adequate treatment of active urinary tract infection, and the presence of cardiopulmonary compromise unsuitable for surgery. The objective of the laparoscopic surgery is to provide a tension-free, watertight repair with a funnel-shaped drainage product to relieve clinical symptoms and to preserve renal function.

Techniques. Several laparoscopic techniques for pyeloplasty have been described in the literature including the standard transperitoneal approach (including transmesenteric), retroperitoneal approach, anterior extraperitoneal approach, laparoendoscopic single-site surgery (LESS) approach, and robotic-assisted approach. For each approach, a dismembered Anderson-Hynes pyeloplasty, which is preferred by most surgeons, or one of the nondismembered methods such as Y-V plasty and flap pyeloplasty (Culp) analogous to those described for the open pyeloplasty can be used.

Transperitoneal Laparoscopic Approach. The initial transperitoneal approach to laparoscopic pyeloplasty was first described by [Schuessler and colleagues \(1993\)](#) and [Kavoussi and Peters \(1993\)](#), and this approach has been the most widely used laparoscopic

method owing to its associated large working space and familiar anatomy. Before the laparoscopic portion of the procedure, cystoscopy with retrograde pyelography may be first performed to define the anatomy and confirm the diagnosis, followed by placement of a ureteral stent and a urethral Foley catheter. Alternatively, the surgeon may place a stent laparoscopically in an antegrade fashion after incising the UPJ. The patient is placed in a 45-degree lateral decubitus position, and access to the peritoneal cavity is obtained via either the Veress needle or the Hasson access technique. Three to five laparoscopic ports are placed after the creation of CO₂ pneumoperitoneum. Typically the umbilical port is for laparoscope use. Colonic mobilization to expose the retroperitoneal structures is the initial step of the laparoscopic procedure, although the transmesenteric approach without bowel mobilization has been reported if the renal pelvis or ureter can be readily recognized through the descending colonic mesentery ([Romero et al, 2006](#)). In a nontransmesenteric approach, after medial mobilization of the colon, the ureter is identified and dissected in the cephalad direction to achieve mobilization of the ipsilateral proximal ureter, UPJ, and renal pelvis ([Fig. 49-14A](#)). Extensive dissection of the ureter and excessive electrocautery use in close proximity to the ureter should be avoided to minimize injury to its vascular supply. At this time, the anatomy of the proximal ureter, renal pelvis, and nearby vasculature are carefully examined to determine the cause of the UPJO and the appropriate type of surgical repair. The general methods and principles of various types of surgical repair for laparoscopic pyeloplasty are identical to those described for open pyeloplasty. If dismembered pyeloplasty is to be performed, which is suitable for the presence of crossing vessels, the renal pelvis is first transected circumferentially above the UPJ and the lateral aspect of the proximal ureter is spatulated ([Fig. 49-14B](#)). The renal pelvis and proximal ureter are then transposed to the opposite side of the crossing vessel, if such vessel is present, and the ureteropelvic anastomosis is then completed with intracorporeal suturing techniques ([Fig. 49-14C and D](#)). If the surgeon opted for antegrade laparoscopic stent placement, this can be accomplished by passing a wire down

Figure 49-14. Transperitoneoscopic view of a patient undergoing a right robotic laparoendoscopic single-site pyeloplasty. Patient's head is to the right of the images. A, A lower pole crossing vessel is being mobilized off the anterior surface of the ureteropelvic junction (UPJ). B, The right proximal ureter being transected sharply after complete mobilization of the proximal ureter and UPJ. C, Percutaneous antegrade placement of a double-J ureteral stent through a small puncture in the subcostal region (not shown). D, Completion of the anterior portion of the ureteropelvic anastomosis.

the ureter through either the upper quadrant port or a 14-gauge angiocatheter passed through the subcostal region. Clamping the Foley catheter and allowing the bladder to fill before wire passage can facilitate this process. After the wire has been placed, a stent can be inserted over the wire using the pusher. Watching for drainage of urine through the stent perforations can be a helpful sign that the distal end of the stent is well-positioned in the bladder and is another reason to consider clamping the catheter until the stent is in place. In the presence of redundant renal pelvis, reduction pyeloplasty may be performed by excising redundant renal pelvic tissue and closing the pyelotomy. The actual laparoscopic suturing maneuver can be accomplished either freehand or with a semiautomated device (Endo Stitch, Covidien, Norwalk, CT). Either continuous running or simple interrupted sutures may be used in the dismembered laparoscopic pyeloplasty, typically with 4-0 absorbable suture. A surgical drain is placed after the completion of the anastomosis, and one of the trocar sites is typically used as the drain exit site.

Transmesenteric Modification of the Transperitoneal Approach.

In select cases, it may be possible to forgo the initial step of colonic mobilization to reveal the UPJ by instead carefully opening the mesocolonic mesentery directly over the UPJ, being careful not to damage any mesenteric or crossing vessels. After incision of the mesentery, the UPJ is mobilized and reconstructed in the same fashion as the standard retrocolic approach described earlier. To use the transmesenteric approach, the dilated renal pelvis must be well visualized, and this is more often possible in thinner, younger patients with less adipose in their mesenteries. Also, preoperative stent placement typically deflates the renal pelvis and may obscure its visualization in this approach. Because the colon is not reflected, operative times using the transmesenteric approach may be shorter (Romero et al, 2006; Castillo et al, 2007; Shadpour et al, 2012). Some authors have reported a shorter

hospital stay in transmesenteric approach patients, theorizing an earlier return of bowel function owing to minimal bowel manipulation during surgery (Romero et al, 2006; Porpiglia et al, 2008; Shadpour et al, 2012).

Vascular Transposition. An alternative approach has been described to treat an obstruction related to lower pole crossing vessels, also known as the *vascular hitch*, in which the lower pole vessels are mobilized and moved to a more cranial position overlying the renal pelvis rather than the UPJ without dismembering the UPJ itself (Meng and Stoller, 2003; Simforoosh et al, 2005; Masood et al, 2009; Sakoda et al, 2011). The majority of the reports on this approach describe its use in the pediatric population, although a series of 42 patients ranging in age from 7 to 69 years reported a 90% success rate (Nouralizadeh et al, 2010). Gundeti and colleagues (2008) performed vascular transposition procedures in 20 children with a 95% success rate at a mean of 22 months' follow-up. However, Nerli and coauthors (2009) noted the uncertainty as to whether the crossing vessels are the sole cause of obstruction as a possible reason for the failure they noted in a 9-year-old on whom they performed a vascular hitch.

Retroperitoneal Laparoscopic Approach. The initial retroperitoneoscopic approach to pyeloplasty was first reported by Janetschek and colleagues (1996). Cystoscopy with retrograde pyelography and ureteral stent placement are first performed as described earlier. For the retroperitoneal approach, the patient is usually positioned in the flank position with the use of flexion and elevation of the kidney rest. Following Hasson access technique to enter the retroperitoneum, a retroperitoneal working space can be created with balloon dilation. After CO₂ pneumoretroperitoneum, three or four laparoscopic ports are used to perform the laparoscopic pyeloplasty. The ureter is usually identified early in the procedure, and the dissection, mobilization, and UPJ repair steps are identical to those described for the transperitoneal approach.

Anterior Extraperitoneal Laparoscopic Approach. The anterior extraperitoneal laparoscopic approach to pyeloplasty was first described by Hsu and colleagues (2003). Cystoscopy with retrograde pyelography and ureteral stent placement are first performed as described earlier. For the anterior extraperitoneal approach, medial mobilization of the peritoneal sac containing the bowel contents en bloc is performed. Subsequently, full exposure of the anterior aspects of the retroperitoneal structures including the ipsilateral ureter and kidney comes into view. The proximal ureter, UPJ, and renal pelvis are identified, dissected, mobilized, and repaired as in the transperitoneal laparoscopic pyeloplasty. The entire procedure is completed in an extraperitoneal manner. A surgical drain is similarly placed at the end of the procedure.

Robotic-Assisted Laparoscopic Approach. The robotic-assisted laparoscopic pyeloplasty in the experimental setting was first reported by Sung and colleagues (1999). Its feasibility was subsequently confirmed with worldwide clinical application in recent years (Gettman et al, 2002; Palese et al, 2005; Mufarrij et al, 2007; Schwentner et al, 2007; Yanke et al, 2008). The most widely used robotic system in the clinical setting today is the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA), and the reported benefits of the robotic system include enhanced 3D vision, motion scaling, tremor reduction, improved dexterity, and increased range of motion. Typically the procedure is performed in a transperitoneal manner providing a larger working space for the robotic arms, although the feasibility of the retroperitoneal approach has been demonstrated (Kaouk et al, 2008; Cestari et al, 2010). A ureteral stent may be placed in a cystoscopic retrograde or laparoscopic antegrade manner. In both transperitoneal and retroperitoneal approaches, at least four trocars are used in a robotic-assisted procedure, including three for the robotic arms (including one for the camera) and one for the surgical assistant to perform suction, irrigation, retraction, and suture introduction. After the initial laparoscopic access and trocar placement, the robotic system is placed in close proximity to the operating table and the robotic arms are attached to the laparoscope and specifically designed laparoscopic instruments. The surgeon at the console operates via the control of the robotic arms, while the assistant remains at the bedside

and performs suction, retraction, exchange of laparoscopic instruments, suture needle introduction, and removal. The general surgical steps are identical to those described for non-robotic-assisted laparoscopic pyeloplasty.

Laparoendoscopic Single-Site Surgery Approach. Since the adoption of laparoscopic and robotic techniques, LESS has been developed in an effort to further decrease surgical invasiveness and improve morbidity (Kaouk et al, 2011). Proponents of the LESS approach suggest it may offer patients improved cosmetic outcomes by decreasing the number of ports from three, four, or five to a single periumbilical incision that is often hidden (Fig. 49-15). In LESS, all the instruments are inserted through a single location. This approach abandons the common laparoscopic principle of triangulation of the ports and results in ergonomic challenges and the clashing of instruments as they compete for space in a limited working envelope. Although this approach increases the level of complexity in performing the procedure, in experienced hands, complication rates of LESS pyeloplasty are similar to those with other minimally invasive approaches (Rais-Bahrami et al, 2013; Tugcu et al, 2013). Pyeloplasty is particularly appealing for LESS because there is no sizeable specimen to be extracted and the incisions can be kept small. However, laparoscopic suturing can be quite challenging in LESS, and some authors report using an accessory subcostal needlescopic instrument and port to facilitate anastomotic suturing.

Typically, a 2.5- to 3-cm intraumbilical or periumbilical incision is made using the Hasson technique. A variety of purpose-built LESS port devices are commercially available. Alternatively, three separate 5-mm ports can be placed in individual incisions inside the umbilicus. A 5-mm laparoscope is commonly used in LESS to reduce instrument conflict, and a right-angle adapter for the light cord can also be helpful to reduce external conflicts with other operating instruments. Various bent and articulating instruments are available to help reduce instrument conflicts ("sword fighting") inside the abdomen. Some surgeons have found a deflecting laparoscope to be helpful as well.

The technical challenges of LESS suturing have led some urologists to apply the robotic platform to LESS pyeloplasty. Just as the

Figure 49-15. A, Postoperative photograph of the abdomen of a patient with left-sided laparoscopic dismembered pyeloplasty. Note the four small scars from the laparoscopic procedure. B, Postoperative appearance of the scar from a right-sided robotic laparoendoscopic single-site pyeloplasty, performed through a single incision at the umbilicus.

articulating instrumentation can shorten the learning curve and facilitate anastomotic reconstruction in standard robotic pyeloplasties, robotic LESS has been reported by several authors as having ergonomic advantages over standard LESS (Desai et al, 2009; Stein et al, 2010; Cestari et al, 2012; Olweny et al, 2012; Tobis et al, 2013). Purpose-designed equipment for robotic LESS remains limited at this time, but future technologic advances may further adoption of these advanced techniques. Renal functional outcomes of both LESS and robotic LESS pyeloplasty have been reportedly excellent, with symptomatic and radiographic success seen in 93% of patients in a recent study by Harrow and colleagues (2013).

Postoperative Care and Complications. Typically, a clear liquid diet is initiated on postoperative day 1 and advanced rapidly after minimally invasive pyeloplasty. Perioperative prophylactic antibiotic coverage is maintained. The Foley catheter is usually removed 24 to 36 hours postoperatively, and the surgical drain is removed before hospital discharge if the drain output remains negligible. If the drain output increases after the Foley catheter removal, the Foley catheter should be replaced for 7 days to eliminate urinary reflux along the stent in the treated ureter and decrease urinary extravasation at the ureteropelvic anastomosis. The ureteral stent is typically removed 4 to 6 weeks later in an outpatient setting, and follow-up including the use of imaging studies such as diuretic renal scan is performed as for an open pyeloplasty. Most of the complications of laparoscopic pyeloplasty are similar to those of general laparoscopic procedures including colonic injury, hemorrhage, ileus, pneumonia, congestive heart failure, thrombophlebitis, and urinoma formation. In the first 100 cases of laparoscopic pyeloplasty performed at Johns Hopkins (Jarrett et al, 2002), such complications occurred in 12% of the patients. Another large-scale review involving 189 cases of laparoscopic pyeloplasty identified an approximately 2% to 2.3% intraoperative complication rate and a 12.9% to 15.8% postoperative complication rate (Rassweiler et al, 2008).

Results

Open Approach. The overall success of open dismembered pyeloplasty has been favorable in the literature. In a retrospective review, Persky and colleagues (1977) noted that none of their 109 dismembered pyeloplasties for UPJO required subsequent nephrectomy. In another retrospective review involving 111 patients with UPJO undergoing open surgical repair over a 15-year-period, Clark and Malek (1987) found 95% success in resolution of clinical symptoms and 91% success in decompression of pelvicalyceal system on urography after one surgical repair. Of the 111 patients with open pyeloplasty, 95 patients (86%) underwent dismembered pyeloplasty. Examining the functional outcomes on the basis of split-function analysis from preoperative and postoperative renal scans, O'Reilly (1989) found that open Anderson-Hynes dismembered pyeloplasty arrested functional deterioration in almost every case and improved function significantly in the majority in 26 consecutive patients with UPJO.

Minimally Invasive Approaches. Most of the published laparoscopic pyeloplasty reports have used the classic Anderson-Hynes dismembered technique because most laparoscopic surgeons attempt to duplicate the well-established principles of open surgery (Bauer et al, 1999; Janetschek et al, 2000; Eden et al, 2001; Soulie et al, 2001; Jarrett et al, 2002; Turk et al, 2002; Inagaki et al, 2005; Bachmann et al, 2006; Rassweiler et al, 2008). The overwhelming majority of patients in these recent series had primary laparoscopic pyeloplasties, and the mean operative times were in the range of 119 to 252 minutes. In the experienced hands, the entire procedure can be consistently performed in less than 3.5 hours (Jarrett et al, 2002), reflecting greater confidence in intracorporeal suturing and knot tying. Perioperative complication rates are low, ranging from 2% to 15.8%, demonstrating the safety of the laparoscopic procedure. Open conversion rates are also low, in the range of 0% to 5.5%. Furthermore, blood transfusion risks are low, being limited to anecdotal reports. Postoperative analgesic use is usually minimal. Mean length of hospital stay ranges from 2.6 to 4.5 days, and the average has decreased to 3.8 days in the series reported since 2000. With mean follow-up times of 14 to 26 months, the rates of surgical

success (defined as durable clinical and/or radiographic success) reach the range of 87% to 99%, with the majority of contemporary series reporting success rates of greater than 95%. The safety and efficacy of laparoscopic pyeloplasty have also been demonstrated in the pediatric population, including patients younger than 1 year (Metzelder et al, 2006).

Most failures from laparoscopic pyeloplasty occur in the first 2 years, although up to 30% of failed cases may occur after 2 years postoperatively (Madi et al, 2008). For the patients in whom laparoscopic pyeloplasty fails, open surgery has been used as a salvage procedure, with success rates of approximately 86% (Thomas et al, 2005). However, most patients can be well managed with endoscopic intervention such as endopyelotomy, with success rates of approximately 70% (Varkarakis et al, 2004).

More data on robotic-assisted laparoscopic pyeloplasty have emerged recently (Table 49-1) (Palese et al, 2005; Mufarrij et al, 2007; Schwentner et al, 2007; Yanke et al, 2008). As in the conventional laparoscopic studies, the overwhelming majority of the patients in these recent series had primary robotic-assisted laparoscopic pyeloplasties. The mean operative times are in the range of 100 to 299 minutes. Perioperative complication rates are low (3% to 24%). Open conversion rates are also relatively low (0% to 6.8%). Postoperative analgesic use is typically minimal. Mean length of hospital stay is in the range of 2.2 to 2.8 days. With mean follow-up times of 11 to 39.1 months, the rates of surgical success (defined as durable clinical and/or radiographic success) are in the range of 94.7% to 100%. These results were similar to those from the historic laparoscopic series in the literature. The feasibility of the robotic approach has also been demonstrated in pediatric patients (Atug et al, 2005b; Lee et al, 2006). The additional reported benefits provided by the robot include better 3D magnification, increased range of motion, and ease of dissection and suturing. However, the value of the robot in the setting of clinical pyeloplasty remains controversial and has been addressed by one recent study (Link et al, 2006). In this study comparing robotic and laparoscopic pyeloplasty in a prospective manner, the mean operative time and total room time for robotic cases were found to be significantly longer than for laparoscopic cases by 19.5 and 39 minutes, respectively. Robotic cases were also found to be more costly than laparoscopic cases (2.7 times) owing to longer operative time, increased consumables costs, and depreciation of the robot system. In the hands of experienced laparoscopic surgeons, the use of the robot does not seem to provide significant clinical or cost advantage compared with the conventional laparoscopic approach. In addition to cost, other concerns related to robotic-assisted laparoscopic pyeloplasty include limited instrumentation and need for experienced bedside laparoscopic assistance (Peschel et al, 2004).

To date, no prospective randomized trial has been performed comparing laparoscopic and open pyeloplasty. The unwillingness of the patients to undergo randomization because of the different levels of perceived invasiveness appears to be the most significant barrier to completing such studies. Although the success rates of pyeloplasty are, in general, high, late failures can occur and long-term follow-up may be helpful in identifying these patients. DiMarco and colleagues (2006) reported that success rates of pyeloplasty in their series of 175 patients dropped from 85% at 3 years to 75% at 10 years, lower than they anticipated.

Primary UPJO associated with renal anomalies such as horseshoe kidneys and pelvic kidneys has also been managed with laparoscopic pyeloplasty safely and successfully (Janetschek et al 1996; Hsu et al 2003; Bovie et al 2004). Furthermore, secondary UPJO has similarly been managed with success. In a retrospective review, Sundaram and colleagues (2003) identified 36 cases of laparoscopic transperitoneal pyeloplasty for secondary UPJO, mostly following failed retrograde or antegrade endopyelotomies. Mean operative time was 6.2 hours, longer than the reported times associated with primary UPJO. Open conversion was necessary in 1 patient, and postoperative complication occurred in 8 patients. With a mean follow-up of 21.8 months, the overall success rate involving a greater than 50% decrease in pain, a patent UPJ, and stable or improved function of the affected renal unit was 83% (30 of 36 patients).

TABLE 49-1 Comparative Series of Robotic versus Laparoscopic Pyeloplasty

AUTHOR, YEAR		n	MEAN AGE (yr)	EBL (mL)	OR TIME (min)	DURATION OF FOLLOW-UP			HOSPITAL STAY (DAYS)	COMPLICATIONS	SUCCESS RATES
						(MONTHS)	(MONTHS)	(MONTHS)			
Link et al, 2006	LP	10	38.0	NSD	80.7 ± 21.9*	5.6				None	100% (authors note short follow-up limits meaning of success)
	RAP	10	46.5	NSD	100.2 ± 9.1*	5.6				10% (1 delayed urine leak)	100%

*Significant difference, $P = .018$.

†LESS LP versus LESS RAP.

EBL, estimated blood loss; LESS, laparoendoscopic single-site surgery; LP, laparoscopic pyeloplasty; NR, not reported; NSD, no significant difference; OR, operating room; Peds, pediatric cases only; RAP, robotic assisted pyeloplasty.

Shapiro and colleagues (2009) identified 9 cases of laparoscopic transperitoneal pyeloplasty for secondary UPJO after a failed open procedure. Mean operative time was 204 minutes. At a median follow-up of 66 months, 89% (8 of 9) patients had clinical and radiologic resolution of UPJO, with stable renal function, pain-free status, and patent UPJ.

Special Situations of Laparoscopic and Robotic-Assisted Laparoscopic Management of Ureteropelvic Junction Obstruction

Laparoscopic and Robotic-Assisted Laparoscopic Ureterocalicostomy. Ureterocalicostomy has been completed successfully via both laparoscopic and robotic-assisted laparoscopic approaches. Gill and colleagues (2004) performed laparoscopic ureterocalicostomy in two patients with UPJO associated with small renal pelvis and dilated lower pole calix. In both patients a double-J ureteral stent was first placed into the ipsilateral ureter cystoscopically. With the patient in a 45- to 60-degree flank position, a transperitoneal approach using three or four ports was used to gain access to the ipsilateral renal unit laparoscopically. A circular rim of the tip of the thin lower pole renal parenchyma was identified and excised. The UPJ was transected, followed by ligation of the renal pelvic opening. The ureter was spatulated laterally, and end-to-end ureterocalyceal anastomosis with mucosa-to-mucosa apposition over the preplaced double-J stent was performed with freehand intracorporeal suturing and knot-tying techniques. The general reconstructive principles are identical to those of open ureterocalicostomy described previously, including the need to achieve tension-free, watertight, dependent drainage.

The largest series of laparoscopic ureterocalicostomies reports outcomes in six procedures. All six remain successful radiographically at a mean of 30 months' follow-up, and there were no major complications (Arap et al, 2014).

Casale and colleagues (2008) reported successful robotic-assisted laparoscopic ureterocalicostomy in nine pediatric patients, following the identical reconstructive principles described earlier. Mean operative time was 168 minutes, and feasibility of the use of the robot was well demonstrated. All patients were found to have no evidence of obstruction on diuretic radionuclide imaging at 12 months postoperatively.

Laparoscopic and Robotic-Assisted Pyeloplasty with Concomitant Pyelolithotomy. Presence of calculi in the setting of UPJO can be managed laparoscopically with success. In a retrospective review, Ramakumar and colleagues (2002) reported 20 cases of laparoscopic pyeloplasty with concomitant extraction of renal stones through the pyelotomy site under laparoscopic guidance. In the series, extraction of the calyceal stones was assisted by the use of a flexible cystoscope introduced through a 10- to 12-mm port site. At a mean follow-up of 3 months, 90% of patients were stone free, and 90% patients had patent UPJ radiographically. In another retrospective review, Stein and colleagues (2008) reported 15 cases of laparoscopic pyeloplasty with concomitant pyelolithotomy, involving the use of laparoscopic graspers, flexible cystoscopes, and/or laparoscopic irrigation. The overall stone-free rate was 80%. Robotic-assisted laparoscopic pyeloplasty with concomitant pyelolithotomy, using similar instruments including laparoscopic graspers, has also been demonstrated in 8 patients (Atug et al, 2005a). To complete the pyelolithotomy, one of the robotic arms was temporarily undocked to allow passage of a flexible nephroscope into the renal pelvis to gain visualization of the stones in the collecting system. In this small series, all patients were rendered stone free.

Laparoscopic Dismembered Tubularized Flap Pyeloplasty. Presence of a significant upper ureteral defect after the excision of UPJ stricture may also be managed laparoscopically with success. Kaouk and colleagues (2002) described a case of laparoscopic pyeloplasty for secondary UPJO, in which a 3-cm upper ureteral defect was found after excision of the long stricture. Using a four-port transperitoneal approach, a wide-base renal pelvic flap was created and tubularized to bridge the defect, using intracorporeal freehand

suturing techniques. At a 2-month follow-up, excretory urography and diuretic renal scan confirmed a widely patent upper ureter.

Laparoscopic Calicovesicostomy. Presence of a large-capacity bladder in the setting of UPJO associated with a low-lying obstructed renal unit can be managed successfully using an unconventional laparoscopic reconstructive strategy. Hsu and colleagues (2006) described a case of laparoscopic management of UPJO involving a horseshoe kidney with a unilateral hydronephrotic yet functioning lower pole moiety, ipsilateral ureteral duplication with high bifurcation, and complex anomalous renal vasculature. Rather than performing tedious anatomic dissection and complex ureteral reconstruction in such a scenario as required in conventional laparoscopic pyeloplasty, a nephrotomy was created at the most dependent portion of the hydronephrotic lower pole moiety and then laparoscopically anastomosed to the bladder dome vesicostomy using intracorporeal freehand suturing and knot-tying techniques. At the 4-month follow-up, patent calicovesicostomy was confirmed endoscopically and clinically.

KEY POINTS: LAPAROSCOPIC AND ROBOTIC INTERVENTION

- Transperitoneal laparoscopic approach is the most widely used method owing to its associated large working space and familiar anatomy.
- Retroperitoneal laparoscopic approach and anterior extraperitoneal approach rely on creation of a working space using manual or balloon dilation.
- Laparoscopic management of UPJO has been shown to provide a low perioperative complication rate, a short hospital stay, and success rates greater than 95% in experienced hands.

Other Reconstructive Procedures Involving the Ureteropelvic Junction (Non-Anderson-Hynes)

Although the Anderson-Hynes dismembered pyeloplasty is the most commonly performed technique for reconstruction of the UPJ, other techniques or modifications may be useful in particular situations as dictated by patient anatomy. These variations can in many cases be performed through either open or minimally invasive approaches, depending on the skill level of the surgeon.

Flap Procedures

Foley Y-V Plasty

Indications. The Foley Y-V plasty was originally designed for repair of an UPJO. Secondary to a high ureteral insertion. Like other flap techniques, however, its use has in general been replaced by the more versatile dismembered pyeloplasty. As with other flap techniques, the Foley Y-V plasty is specifically contraindicated when transposition of lower pole vessels is necessary. In situations requiring concomitant reduction of redundant renal pelvis, this technique is also of little value.

Technique. In Foley Y-V plasty, the renal pelvis and proximal ureter are first exposed, and a widely based triangular or V-shaped flap is outlined with methylene blue or fine stay sutures. The base of the V is positioned on the dependent, medial aspect of the ipsilateral renal pelvis and the apex at the UPJ. The incision from the apex of the flap (the stem of the Y) is then performed along the lateral aspect of the proximal ureter. The surgical incision in the ureter should be long enough to completely traverse the area of stenosis and extend for several millimeters into the normal-caliber ureter (Fig. 49-16A). The renal pelvic flap and ureterotomy are then created. A fine scalpel blade is used for the initial pelvic incision, after which Potts or fine Metzenbaum scissors are used to complete the flap and ureterotomy (Fig. 49-16B). An internal ureteral stent is placed and the repair performed over it. First, the apex of the pelvic flap is approximated to the apex (inferior aspect) of the

Figure 49-16. A, Foley Y-V plasty is best applied to a ureteropelvic junction (UPJ) obstruction associated with a high insertion of the ureter. The flap is outlined with tissue marker or stay sutures. The base of the V is positioned on the dependent, medial aspect of the renal pelvis and the apex at the UPJ. The incision from the apex of the flap, which represents the stem of the Y, is then carried along the lateral aspect of the proximal ureter well into an area of normal caliber. B, The flap is developed with fine scissors. The apex of the pelvic flap is then brought to the most inferior aspect of the ureterotomy incision. C, The posterior walls are then approximated using interrupted or running fine absorbable suture. D, The anastomosis is completed with approximation of the anterior walls of the pelvic flap and ureterotomy.

ureterotomy incision using fine absorbable suture. The posterior walls are then approximated using fine interrupted or running suture (Fig. 49-16C). Interrupted technique is likely to minimize pursing or buckling of the suture line, as well as local tissue ischemia. Anastomosis of the anterior walls is then performed, thereby completing the surgical repair (Fig. 49-16D).

Culp-DeWeerd Spiral Flap

Indications. In general, the Culp-DeWeerd spiral flap is best suited for large, readily accessible extrarenal pelves in which the ureteral insertion is already in a dependent, oblique position. Although most of these patients are also good candidates for a standard or reduction dismembered pyeloplasty, the spiral flap may be of significant value when both UPJO and a relatively long segment of proximal ureteral narrowing or stricture occur in the same setting.

Technique. The spiral flap is first outlined with a broad base positioned obliquely on the dependent aspect of the renal pelvis. To maximize preservation of the flap blood supply, the base is placed in a position anatomically lateral to the UPJ, that is, between the ureteral insertion and the renal parenchyma. The pelvic flap itself may be spiraled posteriorly to anteriorly or vice versa. In either case, the anatomically medial line of incision (farthest from the parenchyma) is carried down the proximal ureter, completely traversing through the obstructed segment (Fig. 49-17A). Appropriate placement of the apex of the flap is determined by the length of flap needed. This, in turn, depends on the length of proximal ureter to be bridged. The longer the flap required, the farther away the apex will be from the base. However, to preserve vascular integrity of the flap, the ratio of flap length to width should not be greater than 3:1. In general, the outline of the flap should be made longer than what may initially be perceived as necessary, because the flap will shrink once the pelvis is incised. If the flap is found to be too long, excess length can be reduced by trimming back the apex, thereby preserving its blood supply. Once the flap has been created, the apex is rotated down to the most inferior aspect of the ureterotomy (Fig. 49-17B). The anastomosis with fine absorbable sutures is subsequently performed over an internal stent (Fig. 49-17C).

Scardino-Prince Vertical Flap

Indications. In general, the Scardino-Prince vertical flap technique has limited clinical application. It may be appropriately used only when a dependent UPJ is situated at the medial margin of a large, square ("box-shaped") extrarenal pelvis (Fig. 49-18A). Its use in most instances has been replaced by a standard dismembered

pyeloplasty, although the vertical flap may be preferable for relatively long areas of proximal ureteral narrowing. It is important to note that the vertical flap technique typically cannot produce as long a flap as the spiral flap.

Technique. The Scardino-Prince vertical flap is similar to the spiral flap technique except that the base of the flap is positioned more horizontally on the dependent aspect of the renal pelvis, between the UPJ and the renal parenchyma. The flap itself is created by straight incisions converging from the base vertically to the apex on either the anterior or the posterior aspects of the renal pelvis. The site of the apex and the length of the flap are determined by the length of proximal ureter to be bridged. The medial incision is carried down the proximal ureter, completely traversing through the stenotic area and into normal-caliber ureter, using fine scissors (Fig. 49-18B). The apex of the flap is then rotated down and approximated to the most inferior aspect of the ureterotomy. Finally, the flap is closed with interrupted or running fine absorbable sutures (Fig. 49-18C).

Intubated Ureterotomy

Indications. The Davis intubated ureterotomy, which is rarely used today, was developed for surgical repair of lengthy or multiple ureteral strictures. If these strictures are found in association with UPJO, the intubated ureterotomy may be combined with any of the standard pyeloplasty procedures. However, in such situations the intubated ureterotomy would be best combined with a spiral flap procedure. Compared with the vertical flap, the spiral flap can be made longer, which allows more of the strictured area to be bridged by a pelvic flap, thereby leaving a shorter area to rely on healing by secondary intention. In fact, in this specific clinical setting, any flap technique would be preferable to a dismembered repair, at least with regard to blood supply preservation and subsequent healing.

Technique. A flap is outlined as described previously, with the ureterotomy to be made completely through the long, strictured area (Fig. 49-19A). The flap is then created, with minimal dissection of the ureter to preserve its blood supply. Unlike uncomplicated pyeloplasties, these cases require routine nephrostomy tube drainage to prevent postoperative urinoma formation. Nephrostomy drainage in these cases also allows access for subsequent antegrade radiographic studies during the postoperative period.

On the basis of the original description, the ureteral intubation is achieved with a stenting catheter that is placed across the stenotic area to the distal ureter or bladder. Proximally, it is brought out through the renal cortex alongside a nephrostomy tube. Currently,

Figure 49-17. A, A spiral flap may be indicated for relatively long areas of proximal ureteral obstruction when the ureteropelvic junction (UPJ) is already in a dependent position. The spiral flap is outlined with the base situated obliquely on the dependent aspect of the renal pelvis. The base of the flap is positioned anatomically lateral to the UPJ, between the ureteral insertion and the renal parenchyma. The flap is spiraled posteriorly to anteriorly or vice versa. The anatomically medial line of incision is carried down completely through the obstructed proximal ureteral segment into normal-caliber ureter. The site of the apex for the flap is determined by the length of flap required to bridge the obstruction. The longer the segment of proximal ureteral obstruction, the farther away is the apex because this will make the flap longer. However, to preserve vascular integrity of the flap, the ratio of flap length to width should not exceed 3:1. B, Once the flap is developed, the apex is rotated down to the most inferior aspect of the ureterotomy. C, The anastomosis is then completed, usually over an internal stent, again using fine absorbable sutures.

most urologists use a self-retaining, soft, inert, internal ureteral stent instead. The apex of the flap is brought over the stent as far down as possible on the ureterotomy, and the flap is closed with either interrupted or running absorbable suture (Fig. 49-19B). The distal aspect of the ureterotomy is then left open for secondary healing via ureteral regeneration (Fig. 49-19C).

An antegrade nephrostogram is usually obtained 6 weeks after the surgery. If there is no extravasation, the ureteral stent is removed cystoscopically and an antegrade radiographic study is repeated. When ureteral patency without extravasation is ensured with such study, the nephrostomy tube is clamped and subsequently removed.

Ureterocalicostomy

Indications. Ureterocalicostomy may be used as a primary reconstructive procedure whenever an UPJO or proximal ureteral stricture is associated with a relatively small intrarenal pelvis (Fig. 49-20A).

When the UPJ is associated with rotational anomalies such as horseshoe kidney (Levitt et al, 1981), ureterocalicostomy may be useful to provide completely dependent drainage. Furthermore, ureterocalicostomy is a well-accepted salvage technique for the failed pyeloplasty (Ross et al, 1990).

Technique. The ureter is first identified in the retroperitoneum and dissected proximally with a generous amount of periureteral tissue. For secondary procedures, however, extensive scarring may preclude adequate identification and dissection of the renal pelvis itself (Fig. 49-20B). The kidney is then mobilized to gain access to the lower pole. An important technical point in ureterocalicostomy is that the parenchyma overlying the lower pole calyx must be resected rather than simply incised because a simple nephrotomy may lead to a secondary stricture (Couvelaire et al, 1964).

The proximal ureter is first spatulated laterally, and the ureterocalyceal anastomosis is completed over an internal stent. Leaving an indwelling nephrostomy tube should also be considered in these patients. The first suture is placed at the apex of the ureteral spatulation and lateral wall of the calyx, and the second suture is placed 180 degrees away. The remainder of the anastomosis is then performed using an interrupted open suture technique—that is, each suture placed is left untied until the final one is in place (Fig. 49-20C). This method seems to provide a more accurate anastomosis under direct vision. When the full set of circumferential sutures has been placed, the sutures are secured down together (Fig. 49-20D). The renal capsule is closed over the cut surface of the parenchyma if possible. However, such closure should not be close enough to the anastomosis itself to cause extrinsic compression on the anastomosis. Instead, the anastomosis should be covered with perinephric fat or a peritoneal or omental flap (Fig. 49-20E). A follow-up urogram is usually obtained 1 month after the ureteral stent extraction (Fig. 49-20F).

Reports exist of laparoscopic and robotic ureterocalicostomy (Gill et al, 2004; Korets et al, 2007; Casale et al, 2008). Arap and colleagues (2014) reported 100% success at a mean of 30 months after laparoscopic ureterocalicostomy in six patients.

Salvage Procedures. Failed open pyeloplasty is a challenging problem that is usually best managed initially with an endourologic approach. In some patients, such an approach may not be applicable. In these cases, successful reconstruction can at times be achieved using one of the flap or dismembered techniques already described. The secondary open operative reconstruction may be significantly aided by the placement of a ureteral catheter

Figure 49-18. A, A vertical flap technique may be used when a dependent ureteropelvic junction (UPJ) is situated at the medial margin of a large, box-shaped extrarenal pelvis. In contrast to the spiral flap, the base of the vertical flap is situated more horizontally on the dependent aspect of the renal pelvis, between the UPJ and the renal parenchyma. The flap itself is formed by two straight incisions converging from the base vertically up to the apex on either the anterior or the posterior aspect of the renal pelvis. As for the spiral flap, the position of the apex determines the length of the flap, which should be a function of the length of proximal ureter to be bridged. The medial incision of the flap is carried down the proximal ureter completely through the strictured area into normal-caliber ureter. B, The apex of the flap is rotated down to the most inferior aspect of the ureterotomy. C, The flap is then closed by approximating the edges with interrupted or running fine absorbable sutures.

to aid intraoperative identification and dissection of the ureter and renal pelvis. In these situations, there is often a relatively long length of proximal ureteral stenosis to repair, and wide mobilization of the kidney and ureter is usually a necessity. This helps to bridge the area of stenosis and allows a tension-free secondary pyeloplasty.

Several other options are available for these secondary and often complex repairs. These surgical alternatives include those generally available for any extensive ureteral problem such as ileoureteral replacement and autotransplantation with a Boari flap pyelovesicostomy. For cases in which function of the involved kidney is already significantly compromised and the contralateral kidney is normal, nephrectomy can be considered.

Postoperative Care and Management of Complications. In general, external drains are removed 24 to 48 hours after cessation of urinary drainage, and internal ureteral stents, if placed, are removed on an outpatient basis approximately 4 to 6 weeks after the surgery. If a nephrostomy tube is used, a nephrostogram is obtained no sooner than 7 to 10 days postoperatively, or even later for particularly complicated repairs. If nephrostogram demonstrates a patent anastomosis without obstruction or extravasation, the tube is clamped for 12 to 24 hours and removed if there is no flank pain, fever, or leakage around the tube.

RETROCAVAL URETER

Etiology and Diagnosis

Retrocaval ureter is a rare congenital urologic anomaly. It occurs as a consequence of the persistence of the posterior cardinal veins during embryologic development (Considine, 1966). Its presence should be suspected with the finding of a

characteristic S-shaped deformity on intravenous or retrograde pyelography (Fig. 49-21A). Today, a definitive diagnosis can be made noninvasively using 3D CT imaging (Fig. 49-21B) (Pienkny et al, 1999). Procedural intervention is indicated in the presence of functionally significant obstruction leading to pain or renal function deterioration.

Operative Intervention

Open Surgical Management

The standard repair of retrocaval ureter is open surgical pyelopyelostomy. In this procedure, the ureter, dilated renal pelvis, and inferior vena cava are identified and dissected using the standard open surgical techniques. The dilated renal pelvis is then transected, then the ureter is transposed to its normal anatomic position anterior to the vena cava (Fig. 49-22). Pyelopyelostomy is then performed circumferentially with absorbable sutures in a tension-free, watertight manner. A surgical drain and internal ureteral stent are typically used.

Laparoscopic Surgical Management

Retrocaval ureter has been managed successfully with the laparoscopic approach in the clinical setting as shown by a series of sporadic case reports (Baba et al, 1994; Matsuda et al, 1996; Polascik and Chen, 1998; Salomon et al, 1999; Gupta et al, 2001; Ramalingam and Selvarajan, 2003). Either a transperitoneal or a retroperitoneal approach may be used laparoscopically. A double-J ureteral stent is first placed into the ipsilateral ureter cystoscopically. After transperitoneal or retroperitoneal laparoscopic access has been achieved, the ipsilateral ureter is identified and mobilized off the

inferior vena cava. The ureter is then divided at the most distal segment of the dilated ureter. A redundant segment of dilated proximal ureter and stenotic segment of ureter are excised if present. The ureteral ends are positioned anterolateral to the vena cava, spatulated for 1.5 to 2 cm on opposite ends, and then anastomosed with absorbable sutures applied with intracorporeal suturing techniques over the stent. Tension-free, watertight anastomosis is the objective. A surgical drain is then left in place before formal laparoscopic exit. The surgical drain is typically removed within a few days postoperatively, and the ureteral stent is typically removed 4 to 6 weeks postoperatively.

More recently, retrocaval ureter has been managed successfully with the robotic-assisted laparoscopic approach (Mufarrij et al, 2007; Hemal et al, 2008; Smith et al, 2009). A transperitoneal approach providing a large working space is typically used. The general principles of laparoscopic ureteral dissection, division, transposition, and anastomosis are identical to those described in conventional laparoscopic approach. At least four different ports are involved, including three for the robot and one for the surgical assistant providing suction, irrigation, suture introduction, and retraction.

The overall clinical results of the laparoscopic repair with or without the use of robots in the literature have been favorable,

Figure 49-19. A, Intubated ureterotomy may be of value when a ureteropelvic junction obstruction is associated with extremely long or multiple ureteral strictures. A spiral flap is outlined and developed as described in Figure 49-20. The ureterotomy incision will be carried completely through the long strictured areas or through each of the multiple areas of stricture. B, The flap is developed, taking care to use minimal dissection of the ureter to preserve its blood supply. In contrast to uncomplicated repairs, nephrostomy tube drainage is used routinely. A self-retaining, soft, inert internal ureteral stent is then placed and positioned proximally in the renal pelvis or lower infundibulum and distally in the bladder. The apex of the flap is then brought as far down as possible over the stent on the ureterotomy, and the flap is closed with interrupted or running absorbable suture. C, The distal aspect of the ureterotomy is left open to heal secondarily by ureteral regeneration. A few fine absorbable sutures may be loosely placed to keep the sides of the ureter in apposition to the stent.

Figure 49-20. A, This patient reported progressive right flank pain and was found on this retrograde study to have a ureteropelvic junction obstruction (arrow) associated with a small intrarenal pelvis. This situation may be best managed with a ureterocalicostomy. B, The ureter is identified in the retroperitoneum and dissected proximally as far as possible. The kidney is mobilized as much as necessary to gain access to the lower pole and to subsequently perform the anastomosis without tension. A lower pole nephrectomy is performed, removing as much parenchyma as necessary to widely expose a dilated lower pole calyx. C, The proximal ureter is spatulated laterally. The anastomosis should subsequently be performed over an internal stent, and consideration should also be given to leaving a nephrostomy tube. The initial sutures are placed at the apex of the ureteral spatulation, and the lateral wall of the calyx with a second suture is placed 180 degrees from that. D, Anastomosis is then completed in an open fashion, placing each suture circumferentially (inset) but not securing them down until the anastomosis has been completed. E, Renal capsule is closed over the cut surface of the parenchyma whenever possible. However, the capsule should not be closed near the anastomosis itself because that may compromise the lumen by extrinsic compression. Instead, the anastomosis should be protected with a graft of perinephric fat or a peritoneal or omental flap. F, Intravenous urogram 2 months after right ureterocalicostomy reveals a widely patent ureterocalyceal anastomosis at the lower pole (arrow).

Figure 49-21. A, Retrograde pyelography in a patient with right-sided hydronephrosis. This study reveals a typical S-shaped deformity secondary to the ureter coursing laterally to medially posterior to the inferior vena cava. B, Three-dimensional spiral computed tomography demonstrates the presence of a retrocaval ureter.

Figure 49-22. A, Intraoperative photograph of a patient with retrocaval ureter undergoing surgical repair via a retroperitoneal flank approach. Right side of the photo represents the cephalad direction. Note the dilated proximal right ureter passing behind the inferior vena cava. B, Right ureteropelvic anastomosis has been completed after transection of the right renal pelvis and transposition of the ureter anterior to the inferior vena cava.

indicating minimal postoperative patient morbidity, short convalescence, and anastomotic patency on short-term radiographic follow-up.

KEY POINTS: RETROCAVAL URETER

- Retrocaval ureter results from the persistence of the posterior cardinal veins.
- Retrocaval ureter can be diagnosed using intravenous or retrograde pyelography or 3D CT.
- Procedural intervention is indicated in the presence of functionally significant obstruction, and both open and laparoscopic approaches can be successfully applied.

URETERAL STRICTURE DISEASE

Etiology

Common causes of ureteral stricture formation include ischemia, surgical and nonsurgical trauma, periureteral fibrosis, malignancy, and congenital factors ([Box 49-1](#)). Proper evaluation and treatment of a ureteral stricture is essential to preserve renal function and rule out the presence of malignancy. Although the classic radiographic presentation of a transitional cell carcinoma of the ureter is a radiolucent filling defect within the lumen with the characteristic goblet sign, it may have the same appearance as a benign stricture. In addition, metastatic tumors such as cervical, prostate, ovarian, breast, and colon cancer may appear as a ureteral stricture ([Lau et al, 1998](#)). Although the incidence of ureteral

BOX 49-1 Etiology of Ureteral Stricture

Malignancy (e.g., transitional cell carcinoma, cervical cancer)
 Ureteral calculus
 Radiation
 Ischemia or trauma caused by surgical dissection
 Periureteral fibrosis caused by abdominal aortic aneurysm or endometriosis
 Endoscopic instrumentation
 Renal ablation injury
 Infection (tuberculosis)
 Idiopathic condition

strictures in the general population is unknown, it is clear that the presence of ureteral calculi and associated treatment of stones are risk factors. Roberts and colleagues (1998) evaluated 21 patients with impacted ureteral stones and found that impaction for more than 2 months' duration was associated with a 24% incidence of stricture formation. Any ureteral instrumentation can lead to the development of a ureteral stricture. As advances in ureteroscopic technology have provided smaller, more actively deflecting instruments with digital optics, ureteroscopic procedures have become less traumatic and are now associated with a long-term complication rate of less than 5% (Harmon et al, 1997; Delvecchio et al, 2003; Ambani et al, 2013). Moreover, more urologists are comfortable with endoscopic incisions as a result. Other causes of benign ureteral strictures include radiation; abdominal aortic aneurysm; infections such as tuberculosis and schistosomiasis; endometriosis; and trauma including iatrogenic injury from previous abdominal or pelvic surgery or post-renal ablation injury (ElAbd et al, 1996; Lacquet et al, 1997; Ramanathan et al, 1998; Oh et al, 2000; Johnson et al, 2004). Patients with presumed idiopathic ureteral strictures should be evaluated with CT scan to rule out the presence of an intrinsic ureteral malignancy or a lesion causing extrinsic compression.

Diagnostic Studies and Indications for Intervention

The presence of obstruction on standard CT can identify ureteral stricture disease, but antegrade or retrograde pyelogram, CT urography, or diagnostic ureteroscopy is necessary to define the location and length of the ureteral stricture. Subsequent ureteroscopy with biopsy or barbotage should be performed in any patient in whom the cause of the stricture is not certain. Diuretic renography will provide differential renal function and evaluate the renal unit for functional obstruction. It is important to assess the renal unit for function before starting treatment because endourologic therapies, in general, require 25% function of the ipsilateral moiety to have reasonable success rates (Wolf et al, 1997). Once a ureteral stricture is diagnosed, indications for intervention include the need to rule out malignancy, ongoing renal obstruction, recurrent pyelonephritis, and pain associated with functional obstruction.

Endourologic Options for Intervention**Ureteral Stent Placement**

Ureteral stent placement is effective acutely in treating most ureteral strictures, in particular intrinsic ureteral strictures. Wenzler and colleagues reported good success rates in treating intrinsic ureteral obstruction, with 88% success rates at 26 months (Wenzler et al, 2008). Although intrinsic ureteral strictures can be managed or temporized with ureteral stents, patients with extrinsic ureteral compression eventually require percutaneous drainage or surgical management (Docimo and Dewolf, 1989; Chung et al, 2004).

If the patient is not a candidate for definitive repair or has a poor prognosis, chronic stent placement with periodic stent changes can be considered. In addition, patients undergoing systemic treatments for malignancies can be managed with periodic stent changes. The use of chronic stent placement must be guarded, particularly when treating ureteral obstruction from extrinsic compression because adequate drainage may be short-lived (Docimo and Dewolf, 1989; Chung et al, 2004). Careful monitoring of the upper tracts and patient symptoms is warranted in this subgroup of patients. Rosevear and colleagues (2007) reported an 84% success rate at 16 months in their series using ureteral stents, with 68% of the patients having malignancy. The remainder included patients with retroperitoneal fibrosis (RPF) and other benign extrinsic diseases. The use of tandem ureteral stent placement (two parallel stents) has been shown to be effective in benign and malignant extrinsic ureteral obstruction (Yohannes and Smith, 2001; Elsamra et al, 2013). Elsamra and colleagues reported on 66 patients managed with tandem ureteral stent placement, with stent failure in 12% of patients with malignant obstruction and none with benign ureteral obstruction. Alternatively, tandem ureteral stent placement may be an excellent option in patients in whom single-stent drainage fails.

After initial reports in 2006, the use of metallic stents in patients with malignant ureteral obstruction has gained popularity (Borin et al, 2006). Liatsikos and coauthors reported on 50 patients treated with the full metallic stent, and although concerns arose regarding stent exchange and encrustation, overall the study supported use of the stent at 12-month intervals (Liatsikos et al, 2010). Kadlec and colleagues reported 5-year data showing good results for use of full-length metal stents with up to a 3-year duration of stent drainage of long-term benign and malignant obstruction in select patients (Kadlec et al, 2013). Expandable metallic mesh stents that allow tissue ingrowth have proven to have problems with encrustation, hyperplastic reactions, and tumor ingrowth (Liatsikos et al, 2009).

Alternatively, Papatsoris reported using nonmesh thermoexpandable metallic stents with both drainage and therapeutic benefits, although urinary tract infections, stent migration, encrustation, and obstruction were similarly identified (Papatsoris et al, 2010). Goldsmith and associates found a 35% failure rate of metallic stents in 25 patients undergoing stent placement for malignant obstruction. Persistent obstruction, distal stent migration, and subcapsular hematoma were noted, and at the present time there is no clear consensus regarding the benefits of metallic stents (Goldsmith et al, 2012).

Balloon Dilation

Retrograde Balloon Dilation. Retrograde dilation of ureteral strictures has historically been part of the urologic armamentarium. The technique was rarely definitive and usually required repeated dilations on a regular basis. In the early 1980s angiographic and vascular balloons were introduced into urologic practice, and the technique of balloon dilation with temporary internal stenting became an accepted mode of treatment (Banner et al, 1983; Finnerty et al, 1984).

As for any patient with a ureteral stricture, the indications to intervene include functionally significant obstruction. Contraindications to this approach include active infection or a stricture longer than 2 cm because dilation alone will rarely be successful in this setting. Moreover, any endoscopic technique is likely to fail with strictures greater than 2 cm (Fig. 49-23).

A retrograde approach is indicated whenever access across the strictured area is easily accomplished using transurethral techniques. In general, the procedure begins with a retrograde pyelogram performed under fluoroscopic control to precisely delineate the site and length of stricture. A floppy-tipped guidewire is passed in a retrograde fashion across the strictured area and coiled proximally in the pyelocalyceal system. This is most easily accomplished by passing an open-end catheter up to the level of the stricture to use as a guide for the hydrophilic or floppy-tipped wire. Passage of the open-end catheter through the strictured area over the wire will then aid subsequent passage of a balloon catheter. Techniques for

Figure 49-23. A, Antegrade and retrograde contrast demonstrating a distal ureteral stricture following prior traumatic ureteroscopic stone procedure. B, Image demonstrating complex guidewire access across this long and narrow stricture with retained proximal stones. C, The stricture is greater than 2 cm, and minimal contrast would pass through antegrade. D, Image after ureteral stent placement. This patient required ureteral reimplantation and stone removal.

bypassing difficult areas of obstruction have been described in detail (Mata et al, 1994).

At this point, the open-end catheter is withdrawn and replaced with a high-pressure, 4-cm-long, 5- to 8-mm balloon. Under fluoroscopic control, the balloon catheter is positioned across the strictured area, with proper position ensured by visualization of radiopaque markers at the tips of the balloon. Balloon inflation is then begun, and a waist will be visualized at the strictured area, which will disappear with progressive balloon inflation (Fig. 49-24). After 10 minutes of tamponade, the balloon is deflated and withdrawn. A guidewire is still in place, and this is used to pass an internal stent, which is left indwelling for 2 to 4 weeks. Follow-up diuretic renography is usually performed approximately 1 month after stent extraction and at 6- to 12-month intervals thereafter.

Occasionally, access across the involved area cannot be obtained using fluoroscopic control alone. In such cases direct ureteroscopic visualization can aid initial passage of the guidewire, and the procedure can be continued as described. Alternatively, a low-profile balloon can be passed through the ureteroscope and the stricture dilated under direct vision.

Antegrade Balloon Dilation. At times, retrograde access across a strictured area is impossible. In such cases, access can be obtained using an antegrade approach and fluoroscopic control (Mitty et al, 1983; Banner and Pollack, 1984), with or without direct antegrade ureteroscopic visualization (de Jonge et al, 1986). Percutaneous nephrostomy drainage is established; in cases associated with infection or compromised renal function, percutaneous drainage alone is instituted to allow resolution of infection and return to

baseline renal function. Once that is accomplished, the percutaneous tract is used for access for a fluoroscopically or ureteroscopically guided approach. The procedure is then analogous to a retrograde approach. Under fluoroscopic guidance, an antegrade contrast agent study is used to definitively define the site and length of the stricture. A floppy-tipped guidewire or glidewire is passed antegrade across the level of obstruction; then a balloon catheter is passed, and the balloon is progressively inflated until the waist disappears. The balloon catheter is withdrawn over a wire and replaced with an internal stent, and a nephrostomy tube is also left indwelling. A follow-up nephrostogram is obtained within 24 to 48 hours to ensure proper positioning of a functional internal stent, and at that time the nephrostomy tube can be removed. Alternatively, access can be maintained by the use of an internal-external stent, which can be capped to allow internal drainage.

Results. Initial reports of retrograde and antegrade balloon dilation of ureteral strictures suggested that results were better when the stricture was anastomotic and of relatively short duration and length (King et al, 1984b; Chang et al, 1987; Netto et al, 1990). Goldfischer and Gerber (1997) reviewed the literature regarding results of balloon dilation of ureteral strictures and found reported success rates ranging from 50% to 76%. In that review, the best results were obtained in patients with iatrogenic, non-anastomotic strictures such as those who had undergone ureteroscopic instrumentation. In that setting, a success rate of 85% was achieved compared with a rate of 50% for anastomotic strictures. Alternatively, Ravary and colleagues found a 40% success rate using retrograde balloon dilation in treating inflammatory

Figure 49-24. A, Retrograde study confirms a short stricture at the level of the ureteropelvic junction in this patient with a horseshoe kidney referred after failed ureteroscopic management of a ureteral calculus impacted at that level. B, The stricture has been traversed with a guidewire, over which a high-pressure balloon has been passed. A waist is evident at the level of the stricture during initial balloon inflation. C, Balloon inflation and stricture dilation are complete with disappearance of the waist.

ureteral strictures at 16 months' follow-up (Ravery et al, 1998). Richter and colleagues (2000) reviewed their results with balloon dilation in 114 patients with a minimum 2-year follow-up. As in other series, balloon dilation was more successful for patients with relatively short strictures. In addition, these authors noted the significance of an intact vascular supply on the success of this procedure. Koukouras reported antegrade percutaneous balloon treatment of iatrogenic ureteral strictures with 72% success at 1-year follow-up (Koukouras et al, 2010). One series of transplant ureteral strictures in which percutaneous balloon dilation was used in 14 transplant patients demonstrated 79% success at 29 months. Notably, these were short, anastomotic strictures in patients on immunosuppression (Voegeli et al, 1988). Others report endoureterotomy as the primary treatment option in such cases (Duty et al, 2013). Of note, in experimental models, balloon dilation created longitudinal incisions similar to endoureterotomy, explaining some of the success seen with use of balloon dilation in ureteral strictures (Nakada et al, 1996).

Endoureterotomy

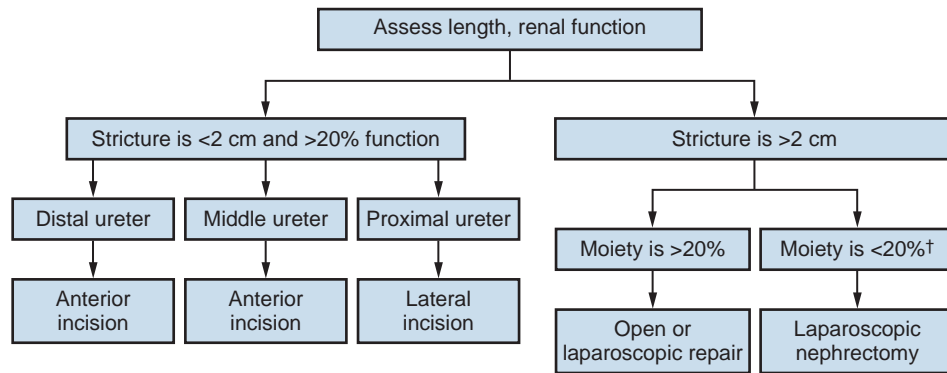

Endoluminal ureteral incision is a logical extension of balloon dilation for "minimally invasive" management of ureteral strictures. As for balloon dilation, access to and across the strictured area can be obtained in a retrograde or antegrade fashion, although a retrograde approach is preferred because it is less invasive. The antegrade approach is indicated when percutaneous access is already present. The procedure is performed under direct vision using ureteroscopic control or it can be guided fluoroscopically using the hot-wire cutting balloon catheter. In general, radiographic follow-up using diuretic renography is recommended for up to 2 years to detect most late failures (Wolf et al, 1997).

Retrograde Ureteroscopic Approach. A retrograde study is performed under fluoroscopic control at the outset of the procedure.

Whenever possible, a floppy-tipped guidewire or hydrophilic glide-wire is passed across the level of obstruction as outlined earlier. If a wire cannot be passed across the strictured area using fluoroscopic control alone, the flexible ureteroscope is passed to the level of obstruction, and the guidewire is advanced through the ureteroscope across the involved area under direct vision. The ureteroscope is then withdrawn, but a safety wire is always left in place across the stricture. The ureteroscope is then reintroduced and passed alongside the guidewire to the level of obstruction.

The position for the endoureterotomy incision is chosen as a function of the level of the ureter involved. In general, lower ureteral strictures are incised in an anteromedial direction, taking care to stay away from the ilioc vessels. In contrast, upper ureteral strictures are incised laterally or posterolaterally, again away from the great vessels (Meretyk et al, 1992) (Fig. 49-25).

The ureterotomy incision itself can be performed using a cold knife (Schneider et al, 1991; Yamada et al, 1995), a cutting electrode (Conlin et al, 1996), or a holmium laser. Today, the holmium laser represents the dominant approach to endoscopic incisions. In all cases the incision is made from the ureteral lumen out to peri-ureteral fat in a full-thickness fashion. Proximally and distally, the endoureterotomy should encompass 2 to 3 mm of normal ureteral tissue. In certain instances the stricture must be balloon dilated to gain access across the stricture (Fig. 49-26). Similarly, the strictures may be balloon dilated after endoincision, to enlarge the incision. Once the endoureterotomy incision is complete, the remaining guidewire is used to pass an internal stent. In general, the larger-diameter stents should be considered because larger stents (8 to 12 Fr) have been associated with improved results (Hwang et al, 1996; Wolf et al, 1997). Similarly, Wolf and colleagues (1997) found benefit in the injection of triamcinolone ureteroscopically after endoureterotomy. Steroids and other biologic response modifiers may eventually have a role in the future in managing select strictures.

OPTIMAL THERAPY FOR BENIGN URETERAL STRICTURES*

*Consider balloon if transplant on immunosuppression.

†Pediatric patients and select patients with renal insufficiency may warrant repair.

G, Endoscopic view of full-thickness incision. H, Fluoroscopic image demonstrating extravasation (arrow). I, Fluoroscopic image after stent placement.

Results. The success of holmium laser endoureterotomy ranges from 66% to 83% in series of more than 10 patients with longer than 12 months' follow-up (Lane et al, 2006; Hibi et al, 2007; Gdor et al, 2008b). There is early evidence that strictures related to stone impaction and prior stone treatment may have lower success rates (56% in one series) than typical benign strictures (Gdor et al, 2008a). Of note, as ureteroscopy and laser lithotripsy continue to grow, more strictures involving impacted stones may be encountered, and this may become a growing clinical problem. Gdor and colleagues reported 67% success in treating transplant ureteral strictures using the holmium laser at 58 months' follow-up, and more recently Mano and coauthors reported an 83% success rate in 26 transplant patients at 44 months' follow-up, with 67% of the patients having undergone initial percutaneous balloon dilation (Gdor et al, 2008b; Mano et al, 2012). **The familiarity of ureteroscopy, coupled with relative availability of the holmium laser, makes retrograde laser endoureterotomy an attractive initial management strategy for ureteral strictures less than 2 cm in length.** Meretyk and Razdan both reported poor results using the retrograde approach in patients with strictures longer than 2 cm (Meretyk et al, 1992; Razdan et al, 2005).

Antegrade Approach. When direct visual ureteroscopic access to the strictured area cannot be accomplished in a retrograde fashion, an antegrade approach may be used. Nephrostomy tube drainage is instituted, and any associated infection or compromised renal function is allowed to resolve before definitive incision. The percutaneous tract is dilated to a size large enough to allow a working sheath through which a flexible ureteroscope is passed. The procedure is then performed in a fashion analogous to a retrograde approach. A safety wire should be in place at all times alongside the ureteroscope, across the obstructed area and coiled distally in the bladder.

Combined Retrograde and Antegrade Approach. Rarely, a ureteral stricture is associated with an area of complete ureteral obliteration across which a wire cannot be passed to allow subsequent balloon dilation or ureteroscopic endoureterotomy. In such cases a combined retrograde and antegrade approach has been described (Cardella et al, 1985; Conlin et al, 1996; Beaghtler et al, 1997; Knowles et al, 2001). The obstructed area is defined radiographically with a simultaneous antegrade and retrograde pyelogram. Endoscopes are passed simultaneously in both a retrograde and an antegrade manner, and the two opposing ureteral ends are localized under fluoroscopic guidance. A working guidewire is then passed from one end of the ureter, through and through to the other lumen, using a combination of fluoroscopic and direct visual control. For completely obliterated ureteral segments, this is most easily accomplished using the stiff end of a guidewire passed through a semirigid ureteroscope via the retrograde approach, although when a semirigid ureteroscope cannot be placed, a flexible ureteroscope or even an open-end ureteral catheter can be used to stabilize the wire from above or below. A "cut to the light" technique can be helpful in this setting. The ureteral segments are aligned as closely as possible under endoscopic and fluoroscopic guidance, and the light source to one of the ureteroscopes is turned off. The light from the opposite ureteroscope is then used to aid incisional restoration of urinary continuity. The strictured area is then recannulated using the stiff end of a guidewire, a small electrocautery electrode, or holmium laser. Once through-and-through control is obtained with a guidewire, a stent is passed and left in place for 8 to 10 weeks. As with other endourologic approaches to ureteral strictures, success rates are inversely related to the length of the strictured area. **Although success rates may be uncertain, internalization of urinary flow, even when dependent on long-term stent placement, can be a quality-of-life advantage for certain high-risk patients.** Knowles and colleagues reported a 90% patency rate at 36 months' follow-up for use of cautery wire balloon incision to treat 10 patients with obliterated distal ureteral segments, 3 of whom required the combined approach (Knowles et al, 2001). Bach and colleagues reported a retrograde blind (fluoroscopically guided) endoureterotomy with a 61% success rate in patients with subtotal ureteral strictures (Bach et al, 2008).

KEY POINTS: ENDOUROLOGIC MANAGEMENT OF URETERAL STRICTURES

- Proper evaluation and treatment of a ureteral stricture are essential to preserve renal function and rule out the presence of malignancy. It is critical to assess the renal unit for function before starting treatment because endourologic therapies typically require 25% function of the ipsilateral moiety.
- The use of chronic stent placement for extrinsic ureteral obstruction must be guarded, because the drainage is often limited. Innovations in stents and stent techniques have led to long-term success in select patients with malignant ureteral obstruction.
- The indications to intervene for ureteral stricture disease include clinical symptoms and functionally significant obstruction. Contraindications to this approach include active infection or a stricture longer than 2 cm.
- Current available reports and the familiarity of ureteroscopy, coupled with relative availability of the holmium laser, make retrograde laser endoureterotomy an attractive initial management strategy for short ureteral strictures.
- The position for the endoureterotomy incision is chosen as a function of the level of the ureter involved. In general, lower ureteral strictures are incised in an anteromedial direction, taking care to stay away from the iliac vessels. In contrast, upper ureteral strictures are incised laterally or posterolaterally, away from the great vessels.

Surgical Repair

Before any surgical repair, it is essential to conduct careful evaluation of the nature, location, and length of the ureteral stricture. Preoperative assessment typically includes an intravenous pyelogram (or antegrade nephrostogram) and a retrograde pyelogram if indicated, because the location and length of the stricture heavily influence the options for repair. Other studies such as a nuclear medicine renogram to assess renal function and ureteroscopy, ureteral barbotage, and/or brushing to rule out carcinoma should be individualized. On the basis of such information, the appropriate surgical procedure can then be planned for the patient (Table 49-2).

Ureteroureterostomy

A short defect involving the upper ureter or mid-ureter, either in the form of stricture or as a consequence of recent injury, is most appropriate for ureteroureterostomy. On the other hand, a lower ureteral stricture is usually best managed by ureteroneocystostomy with or without a psoas hitch or Boari flap. In the transplant setting, a donor ureteral stricture may be managed by a ureteroureterostomy to a healthy, native ureter. Because tension on the anastomosis almost always leads to stricture formation, only short defects should be managed by end-to-end ureteroureterostomy. Determination of whether or not enough ureteral mobility can be achieved to allow tension-free ureteroureterostomy usually cannot be made until the

TABLE 49-2 Bridging Various Ureteral Defect Lengths with Different Reconstructive Surgical Techniques

TECHNIQUE	URETERAL DEFECT LENGTH (cm)
Ureteroureterostomy	2-3
Ureteroneocystostomy	4-5
Psoas hitch	6-10
Boari flap	12-15
Renal descensus	5-8

time of surgery, and thus the urologist must be prepared to pursue other options.

Open Approach. The choice of surgical incision depends on the level of the ureteral stricture. A flank incision is appropriate for the upper ureter. A Gibson or a lower midline incision is suitable for the middle and lower ureter. If the patient has sustained an iatrogenic ureteral injury from a previous surgery performed through a Pfannenstiel incision, the same incision may be used for the ureteral reconstruction. In such a situation, proximal ureteral dissection may be difficult through the Pfannenstiel incision, requiring cephalad extension of the lateral portion of the incision in a “hockey stick” fashion. Extraperitoneal dissection is usually performed except in cases of transperitoneal surgical ureteral injury.

After surgical incision, the retroperitoneal space is developed as the peritoneum is mobilized and retracted medially. Frequently, the ureter can be easily identified as it crosses the iliac vessels. A Penrose drain or vessel loop may be placed around the ureter to assist its atraumatic handling. Direct handling of the ureter with forceps should be minimized. Care should be taken to preserve its adventitia, which loosely attaches the blood supply to the ureter.

During ureteral dissection and mobilization, enough mobility must be achieved to avoid tension after the excision of the diseased ureter. With a gunshot injury, devitalized tissue and an adjacent segment of normal-appearing ureter should be excised to eliminate late ischemia and stricture formation from the blast effect. Once both ends of the ureter have been adequately trimmed to healthy areas, mobilized, and correctly oriented, they are spatulated for approximately 5 to 6 mm. Spatulation is performed for both ureteral segments at 180 degrees apart. If a grossly dilated ureter is involved, it may be transected obliquely and not spatulated to match the circumference of the nondilated segment. A fine,

absorbable suture is placed in the corner of one ureteral segment and the apex of the other, and the two ends of the suture are tied outside the ureteral lumen. The opposite corner and apex are similarly sutured and approximated. The anastomosis may then be completed by running these two sutures continuously and tying them to each other or in an interrupted fashion (Fig. 49-27). A double-J ureteral stent should be placed before completion of the anastomotic closure. Stent placement can be facilitated by passing the wire through one of the side holes in the middle of the stent to straighten and stiffen the stent enough to permit it to pass. Observation of reflux of methylene blue irrigant from the bladder to the ureterotomy can be used to verify the appropriate placement of the distal stent in the bladder. Retroperitoneal fat or omentum may be used to cover the anastomosis.

Laparoscopic or Robotic Approach. A laparoscopic or robotic approach may be offered to patients with ureteral stricture disease. [Nezhat and colleagues \(1992\)](#) first reported laparoscopic management of an obstructed ureter resulting from endometriosis. In this case, ureteroureterostomy was performed laparoscopically over a ureteral stent after resection of the obstructed ureteral site. Most of the studies since that time consist of single case reports or small series. Several reports of laparoscopic ureteroureterostomy to unobstruct a duplicated system in the pediatric population have appeared ([Piaggio and Gonzalez, 2007](#); [Smith et al, 2009](#)). More recently, the robotic-assisted approach has been applied to laparoscopic ureteroureterostomy in a small number of patients ([Mufarrij et al, 2007](#); [Passerotti et al, 2008](#); [Lee et al, 2010](#)). Lee and colleagues reported a series of three robotic ureteroureterostomies, all successful by symptom and nuclear renal scan criteria at an average of 24 months. The overall clinical experience in minimally invasive ureteroureterostomy is limited worldwide. However, in the hands of the

Figure 49-27. A, Spatulated ureteral ends. B, Placement of sutures. C, End-to-end ureteroureterostomy.

experienced surgeon, it appears to be a viable minimally invasive approach applicable to almost any patient with a relatively short area of obstruction.

Postoperative Care. The postoperative care of ureteroureterostomy patients is similar, regardless of surgical approach. A surgical drain is placed, and a Foley catheter is usually left indwelling for 1 to 2 days. The surgical drain may be removed if there is minimal output for 24 to 48 hours. If the surgical procedure is not performed entirely in a retroperitoneal manner, it is important to determine the nature of the fluid from the surgical drain, which can be achieved by checking the creatinine level of the fluid. If there is no urinary extravasation, the drain can then be removed. The double-J ureteral stent is removed endoscopically, usually 4 to 6 weeks postoperatively.

The success rate for a tension-free, watertight ureteroureterostomy is high—greater than 90% (Carlton et al, 1969; Guiter et al, 1985). If a urinary fistula is suspected, a plain abdominal radiograph should first be obtained to verify the position of the double-J stent. The proximity of a drain to the anastomosis should also be checked because it may exacerbate a leak. Suction should be stopped if a suction drain device is used because straight drainage may assist closure of the ureteral leakage site. Reflux from voiding or bladder spasms may also contribute to prolonged urinary extravasation, a problem that can be managed by Foley catheter drainage and anticholinergics. Prolonged urinary leakage from the anastomosis may require the placement of a nephrostomy tube for proximal urinary diversion.

Ureteroneocystostomy

Ureteroneocystostomy to manage vesicoureteral reflux is covered elsewhere in the text. Ureteroneocystostomy without a psoas hitch or Boari flap in an adult is appropriate for injury or obstruction affecting the distal 3 to 4 cm of the ureter. For open ureteroneocystostomy, a lower midline, Pfannenstiel, or Gibson incision may be used, and in general the extraperitoneal approach is preferable. After surgical incision, the ureter is usually identified as it crosses the iliac vessels, dissected distally, and transected at the level of the obstruction. After adequate proximal ureteral mobilization, direct ureteroneocystostomy is performed only if a tension-free anastomosis is possible. Otherwise, a psoas hitch or Boari flap should be used as an adjunct. A direct, nontunneled anastomosis may be performed if postoperative reflux is acceptable. Otherwise, a submucosal tunnel is created for antireflux anastomosis. A double-J stent and surgical drain are used as described earlier for ureteroureterostomy.

The issue of refluxing versus antirefluxing anastomosis in ureteroneocystostomy in adults has been examined previously. In a retrospective review of adult patients with ureteroneocystostomy, no significant difference in the preservation of renal function or risk of stenosis was identified in the refluxing versus antirefluxing procedures (Stefanovic et al, 1991). However, it is unclear if a nonrefluxing anastomosis decreases the risk of pyelonephritis in an adult patient.

Minimally Invasive Ureteroneocystostomy. Successful laparoscopic application to ureteroneocystostomy has been reported by a variety of investigators (Ehrlich et al, 1993; Reddy and Evans, 1994; Yohannes and Smith, 2001; Gözen et al, 2010). In the management of distal ureteral stricture, laparoscopic ureteroneocystostomy is usually performed transperitoneally, incorporating intracorporeal suturing techniques, because it provides a large working space. Ureteral stenting is typically used postoperatively as in open surgery. Although this procedure requires intracorporeal laparoscopic suturing, the overall clinical experience for laparoscopic management of distal ureteral strictures has been increasing over time. Abraham and colleagues reported their experience performing laparoscopic ureteral reimplantation in 36 patients and reported success in all patients at a mean of 16 months' follow-up (Abraham et al, 2011). Overall, the clinical outcomes have been reported to be favorable to and comparable with those of open surgical procedures while providing minimal postoperative morbidity, as in many other laparoscopic urologic procedures. LESS neocystostomy has been reported as well (Khanna et al, 2012).

As is the case for many reconstructive urologic procedures, urologists have reported finding the robotic platform useful in neocystostomy (Fig. 49-28) (Mufarrij et al, 2007; Laungani et al, 2008; Williams and Levillie, 2009). This procedure can typically be performed using a four-arm robotic approach with port placement similar to that of a robotic prostatectomy or with ports shifted slightly cephalad. Isac and colleagues reported similar success rates for robotic and open neocystostomy, with the robotic approach being associated with a significantly shorter hospital stay (3 vs. 5 days, $P = .0004$) and less narcotic use (morphine equivalent, 104.6 vs. 290 mg, $P = .0001$) (Isac et al, 2013). Musch and colleagues reported a robotic approach to be effective even in cases requiring a psoas hitch or Boari flap (Musch et al, 2013).

Open Psoas Hitch

The psoas hitch is an effective method to bridge a defect of the lower third of the ureter. However, a ureteral defect extending proximal to the pelvic brim usually requires more than a psoas hitch alone. Indications include distal ureteral stricture, injury, and failed ureteroneocystostomy (Prout and Koontz, 1970; Ehrlich et al, 1978; Rodo Salas et al, 1991). A psoas hitch may also be used in conjunction with other maneuvers such as a transureteroureterostomy (TUU) in more complicated urinary tract reconstruction. In general, a small, contracted bladder with limited mobility is considered a contraindication. In addition to the preoperative radiographic and endoscopic evaluation described previously, urodynamic studies may provide information regarding detrusor capacity and compliance before the surgery. Bladder outlet obstruction or neurogenic dysfunction, if present, needs to be treated preoperatively.

To gain access to the distal ureter, a Pfannenstiel or lower midline incision is usually used. An extraperitoneal approach is preferred, if possible. In such a scenario, the space of Retzius is developed and the bladder mobilized by freeing its peritoneal attachments and

Figure 49-28. Intraoperative photograph of a patient undergoing a robotic right ureteral neocystostomy for distal ureteral stricture seen in CT urography (A). dividing the vas deferens or round ligament. With traction, the ipsilateral dome of the bladder should be able to reach the level proximal to the iliac vessels. **Additional mobility can be achieved by dividing the contralateral superior vesical artery.** The ipsilateral ureter is identified as it crosses the iliac vessels, is mobilized, and is divided just above the diseased segment. An anterior cystotomy, usually created in a vertical or oblique fashion, is frequently made to assist manual displacement of the bladder toward the ipsilateral ureter. The ureter is delivered into the lumen of the bladder at the ipsilateral superolateral aspect of the dome, followed by the tension-free anastomosis with or without a submucosal tunnel. **The ipsilateral bladder dome is secured to the psoas minor tendon or the psoas major muscle using several absorbable sutures.** Care should be taken to avoid injury to the genitofemoral nerve and the femoral nerve in the vicinity when placing these sutures. Alternatively, psoas fixation may be performed before ureteroneocystostomy. A double-J stent is used usually, followed by closure of cystotomy with absorbable sutures (Fig. 49-29).

Relative to simple ureteroneocystostomy, the psoas hitch can provide an additional 5 cm of length. Relative to the Boari flap, the advantages of psoas hitch include increased technical simplicity and decreased risk of vascular compromise and voiding difficulties. The success rate of ureteroneocystostomy with a psoas hitch is greater than 85% in both adults and children on the basis of reports (Mathews and Marshall, 1997; Ahn and Loughlin, 2001). Complications occur uncommonly but have included urinary fistula, ureteral obstruction, nerve injury, bowel injury, iliac vein injury, and urosepsis (Fig. 49-30).

Laparoscopic Psoas Hitch

Ureteroneocystostomy with psoas hitch has been performed laparoscopically with success (Nezhat et al, 2004). Successful robotic-assisted application has also been reported (Mufarrij et al, 2007; Patil et al, 2008; Schimpf and Wagner, 2009). In general, preoperative ureteral stenting is performed, and the procedure is typically

completed via the transperitoneal approach. Overall, the clinical experience with such procedures is quite limited in the literature. However, on the basis of short-term and intermediate-term follow-up data to date, the clinical outcomes appear to be satisfactory and equivalent in experienced hands.

Open Boari Flap

When the diseased ureteral segment is too long or when ureteral mobility is too limited for a tension-free ureteroureterostomy to be performed, a Boari flap may be a useful alternative. Boari first described the use of this technique in the canine model in 1894. A Boari flap can be constructed to bridge a 10- to 15-cm ureteral defect, and a spiraled bladder flap can reach the renal pelvis in some circumstances, especially on the right side. As with a psoas hitch, evaluation of bladder function and capacity should be performed preoperatively in addition to the ureteral evaluation. Bladder outlet obstruction and neurogenic dysfunction, if present, should be addressed preoperatively. **A small bladder capacity is likely to be associated with difficult or inadequate Boari flap creation, warranting consideration of alternative methods in the preoperative surgical planning.**

In Boari flap procedure, a Pfannenstiel incision may be used at the time of surgery, although a midline incision is preferable and allows easier access to the upper ureter. The bladder is mobilized from its peritoneal attachments, and the umbilical ligaments are divided. The contralateral bladder pedicle is divided and ligated, allowing greater mobility toward the ipsilateral ureter, and the ipsilateral bladder pedicle including the superior vesical artery is preserved. The affected ureter is carefully mobilized, with care being taken to preserve its blood supply. The diseased segment is then excised. After identification of the ipsilateral superior vesical artery or one of its branches, a posterolateral bladder flap is outlined on the basis of this vascular supply. The flap continues obliquely across the anterior bladder wall, with the base of the flap being at least 4 cm in width and the tip of the flap being at least 3 cm in width.

Figure 49-29. A, For a psoas hitch, an anterior cystotomy is performed after bladder mobilization. B, The bladder dome is fixed to the ipsilateral psoas tendon, and the ureteral reimplantation is completed in a tension-free manner.

Figure 49-30. A female patient with right distal ureteral stricture. A, Preoperative retrograde pyelogram showing ureteral dilation proximal to the stricture site. B and C, Postoperative voiding cystourethrogram and intravenous pyelogram after a Boari flap procedure.

The flap length should equal the estimated ureteral defect plus an additional 3 to 4 cm if a nonrefluxing anastomosis is planned. Furthermore, the ratio of flap length to base width should not be greater than 3:1 to help minimize flap ischemia.

After bladder flap creation, the distal end of the flap is pexed to the psoas minor tendon or psoas major muscle with several absorbable sutures. The ureter is delivered through a small opening created in the posterior flap, and a tension-free mucosa-to-mucosa refluxing anastomosis is performed after spatulation of the distal ureteral end. Alternatively, a nonrefluxing tunneled anastomosis can be used. The flap is then tubularized anteriorly and closed using absorbable suture. Furthermore, the ureteral adventitia may be secured to the distal aspect of the flap, and the base of the flap may be secured to the psoas (Fig. 49-31).

The number of reported patients treated with a Boari flap is small, yet the results are good if a well-vascularized flap is used (Ockerblad, 1947; Scott and Greenberg, 1972; Thompson and Ross, 1974; Middleton, 1980; Benson et al, 1990; Motiwala et al,

1990) (Fig. 49-32). Clearly, the most common complication is stricture formation, resulting from either ischemia or excessive tension on the anastomosis. Rare pseudodiverticulum has also been reported (Berzeg et al, 2003). Mauck and colleagues reported success in 9 of 10 patients with proximal ureteral strictures treated with a Boari flap (with or without simultaneous downward nephropexy) at 12.8 months' mean follow-up (Mauck et al, 2011).

Laparoscopic Boari Flap

The laparoscopic Boari flap procedure has been uncommonly yet successfully performed in the clinical setting. Kavoussi and colleagues reported three successful cases for distal ureteral obstruction, in which a transperitoneal approach was used (Fugita et al, 2001). Following the same principles as in open surgery, the bladder flap was created and anastomosed to the ureteral end over a stent in a tension-free, watertight manner. Operative time ranged from 120 to 330 minutes, and blood loss ranged from 400 to 600 mL.

Figure 49-31. A, For a Boari flap, the intended flap is first marked on the anterior and lateral aspects of the mobilized bladder. B, The flap is created, ensuring good vascular supply. C, Ureteroneocystostomy is completed, with the longitudinal bladder tube closure.

Figure 49-32. A, Preoperative nephrostogram of a patient with left proximal ureteral injury after aortobifemoral bypass surgery. B, Postoperative voiding cystourethrogram after a Boari flap procedure.

Two patients were discharged home within 3 days postoperatively, and 1 patient was hospitalized for 13 days for *Clostridium difficile* colitis. With a follow-up of more than 6 months, there was radiographically demonstrated patency of the anastomosis. In this report, the information regarding the length of distal ureteral stricture was not available. More recently, a laparoscopic Boari flap procedure assisted by the robot has been successfully performed (Schimpf and Wagner, 2009; Allaparthi et al, 2010; Yang et al, 2011; Kozinn et al, 2012; Musch et al, 2013). The transperitoneal approach has been used in all cases reported thus far.

Renal Descensus

Renal mobilization, which was originally described by Popescu in 1964, can provide additional length to bridge a defect in the upper ureter or decrease tension on a ureteral repair (Harada et al, 1964; Popescu, 1964; Passerini-Glazel et al, 1994). A transperitoneal, subcostal, midline, or paramedian incision may be used to gain access to the kidney and the appropriate level of the ureter. After entry to the Gerota fascia, the kidney is completely mobilized and rotated inferiorly and medially on its vascular pedicle. The lower pole of the kidney is then secured to the retroperitoneal muscle using several absorbable sutures. Up to 8 cm of additional length may be gained using this technique. In such cases the renal vessels—especially the renal vein—limit the extent to which the kidney can be mobilized. As a solution, the technique for division of the renal vein with reanastomosis more inferiorly to the inferior vena cava may be performed but is rarely applied clinically. Renal descensus may also be combined with other reconstructive techniques such as a Boari flap to repair pan-ureteral strictures. In addition, laparoscopic techniques have been reported (Sutherland et al, 2011).

Intubated Ureterotomy

The Davis intubated ureterotomy has been described previously in this chapter. Because of the development of the more effective surgical treatment alternatives, this procedure is described primarily for historical interest. In general, an intubated ureterotomy is used for a ureteral stricture too long for conventional ureteroureterostomy or ureteroneocystostomy and has been performed to treat strictures up to 10 to 12 cm in length. An innovative modification to this procedure has incorporated a buccal mucosal patch graft in a small number of patients with good results (Naude, 1999).

Open Transureteroureterostomy

The initial clinical application of TUU was described by Higgins (1934). In the management of ureteral stricture, a TUU may be used when ureteral length is insufficient for anastomosis to the bladder (Brannan, 1975). The only absolute contraindication is insufficient length of the donor ureter to reach the contralateral recipient ureter in a tension-free manner. However, any disease process that may affect both ureters represents a relative contraindication. Absolute contraindications include the presence of a diseased recipient ureter or a donor ureter of inadequate length. Relative contraindications include history of nephrolithiasis, RPE, urothelial malignancy, chronic pyelonephritis, and abdominopelvic radiation. Reflux to the recipient ureter, if present, needs to be identified and corrected simultaneously. Therefore a voiding cystogram should be performed preoperatively, in addition to the other imaging and endoscopic studies previously described for thorough evaluation of both ureters.

In performing a TUU, a midline, transperitoneal approach is used to gain access to both ureters. After medial colonic mobilization, the affected ureter is mobilized, preserving the adventitia with the ureteral blood supply, and divided just proximal to the level of obstruction. The contralateral colon is medially mobilized. Only the portion of recipient ureter needed for the anastomosis is exposed, which is typically 5 cm proximal to the level of division of the affected ureter. A tunnel under the sigmoid colon mesentery

is created proximal to the inferior mesenteric artery to avoid ureteral tethering by this vessel, after which the donor ureter is brought through the tunnel to the recipient side. Mobilization of the recipient ureter should be minimized to help preserve the integrity of its vascular supply. An anteromedial ureterotomy is made in the recipient ureter, which is then anastomosed to the spatulated donor ureteral end in a tension-free, watertight manner using either interrupted or running absorbable sutures. A double-J ureteral stent is usually passed from the donor renal pelvis through the anastomosis and into the bladder. A second ureteral stent may also be placed throughout the length of the recipient ureter if the ureter is found to be adequately large in diameter.

The clinical success of TUU has been demonstrated by multiple investigators. Hendren and Hensle (1980) reported 75 cases of pediatric TUU without compromising a single recipient kidney. Hodges and colleagues (1980) reported similar success in a large group of children and adults. However, two patients required revision because of ureteral kinking by the inferior mesenteric artery. The successful application of TUU was further confirmed more recently by Pesce and colleagues (2001). In two other recent studies, nephrectomy for ureteral stenosis was found to be rarely necessary (Mure et al, 2000; Sugarbaker et al, 2003).

Laparoscopic Transureteroureterostomy

A few reports of successful laparoscopic TUU exist, and this may be a viable option in skilled hands, although long-term clinical data to support this technique do not yet exist (Piaggio and Gonzalez, 2007; Kaiho et al, 2011).

Open Ileal Ureteral Substitution

Surgical management of long length of ureteral defect or loss, especially the proximal ureter, is particularly challenging (Benson et al, 1990). Reconstruction of the ureter with tissue lined with urothelium is most preferable because urothelium is not absorptive and is resistant to the inflammatory and potentially carcinogenic effects of urine (Harzmann et al, 1986). Incorporation of other tissue in ureteral repair is, therefore, reserved for situations in which a defect cannot be bridged by other methods or the bladder is unsuitable for reconstruction. In this scenario, ileal interposition has been demonstrated to be a satisfactory option for complicated ureteral reconstruction. On the other hand, the appendix and fallopian tube have been found to be unreliable ureteral substitutes.

Shoemaker reported the first ileal ureter in a woman with tuberculous involvement of the urinary tract in 1909 (Moore et al, 1956). Later, the metabolic and physiologic effects of the ileal ureter were investigated in the canine model (Hinman and Oppenheimer, 1958; Martinez et al, 1965). When an isoperistaltic segment of ileum is directly anastomosed to the bladder, reflux and renal pelvic pressure increase are usually seen only during voiding. The retrograde transmission of intravesical pressure is dependent on the length of ileum segment used in interposition and the voiding pressure. In patients with ileal segments longer than 15 cm, Waldner and colleagues (1999) found no reflux into the renal pelvis in a report involving 19 patients with ileal ureter with refluxing ileovesical anastomosis. Comparing dogs with tapered versus nontapered ileal segments, Waters and colleagues (1981) found no difference in renal perfusion pressure or metabolic derangements.

A large clinical experience in ileal ureter involving 89 patients was reported by Boxer and colleagues (1979). Only 12% of patients with normal preoperative renal function developed significant metabolic problems postoperatively, and preoperative renal function was identified to be an important prognostic factor. In a separate study, nearly half of those with a serum creatinine of greater than 2 mg/dL developed hyperchloremic metabolic acidosis, requiring conversion to a conduit (Koch and McDougal, 1985). In the same study, patients with bladder dysfunction also experienced more complications. No sufficient clinical data exist to establish the superiority of a tapered segment, a nonrefluxing anastomosis, or a shorter, segmental replacement over a standard ileal substitution

(Waters et al, 1981). Therefore, the contraindications to an ileal ureteral substitution are baseline renal insufficiency with a serum creatinine of greater than 2 mg/dL, bladder dysfunction or outlet obstruction, inflammatory bowel disease, and radiation enteritis.

Before the surgical procedure, a full mechanical and antibiotic bowel preparation is often used. A long midline incision is made. The ipsilateral colon is mobilized medially, and the affected ureter is dissected proximally to the level of healthy tissue. The proximal anastomosis may be performed at the level of the renal pelvis if the entire upper ureter is unhealthy. The length of the ureteral defect is measured, and an appropriate segment of distal ileum is chosen. The segment should be at least 15 cm away from the ileocecal valve, and adequate blood supply should be confirmed before harvesting. The mesentery is usually divided more extensively than with a standard ileal conduit to provide greater mobility. Occasionally, a segment of colon may be more accessible than ileum and is harvested using similar surgical principles. In the presence of a scarred or intrarenal pelvis, ileocalicostomy may be performed (McQuitty et al, 1995). In this circumstance, excision of a piece of lower pole renal parenchymal tissue is helpful in preventing stenosis at the anastomosis, as in a typical ureterocalicostomy. After bowel division, the distal end of the ileal segment is marked for orientation, and bowel-to-bowel continuity is reestablished. A small window is made in the colonic mesentery, through which the segment of ileum is delivered laterally. Alternatively, the cecum and ascending colon can be reflected superiorly to avoid mesenteric window creation in performing right ureteral reconstruction. The orientation of the ileal segment is checked to ensure isoperistalsis, and the anastomoses are performed at the level of the renal pelvis or lower pole calyx and at the bladder (Fig. 49-33). Bilateral ileal ureteral substitution may be achieved by using a longer segment that travels intraperitoneally from one kidney to the other and then to the

bladder. An alternative to such is to use two separate bowel segments.

Perioperative complications associated with ileal ureter include early urinary extravasation or urinoma formation and obstruction from edema, a mucous plug, or a kink in the segment. Ischemic necrosis of the ileal segment may occur and should be considered if signs of an acute abdomen are present. Significant electrolyte abnormalities and renal insufficiency are unusual if preoperative renal function is normal. Patients with worsening metabolic abnormalities associated with a progressively dilating ileal ureter should be evaluated for vesicourethral dysfunction. Furthermore, malignancy arising from an ileal ureter segment has been reported in four cases in the literature (Austen and Kalble, 2004), and it is recommended that regular endoscopic examination be performed starting at postoperative year 3 for early detection of such malignancy. However, Bonfig and colleagues (2004) confirmed the safety and reliability of ileal ureter creation for complex ureteral stricture and loss in 43 patients with a mean follow-up of 40.8 months. A more recent study from Wolff and coauthors (2011) reported long-term follow-up in 17 patients undergoing ileal ureteral substitution (median 174 months) and found that 15 patients still had ileal ureters at the end of the study interval, although 3 patients were on dialysis by that time. The mean creatinine value at last follow-up was 1.8 ± 0.6 mg/dL.

Laparoscopic Ileal Ureteral Substitution

The clinical experience in laparoscopic ileal ureteral substitution is limited worldwide, yet this procedure appears to hold significant promise. Gill and colleagues (2000a) reported successful laparoscopic ileal ureter replacement using a transperitoneal, three-port approach. The entire procedure including freehand suturing and knot tying was performed using intracorporeal laparoscopic

Figure 49-33. A, In ileal ureteral substitution, the affected ureter is first identified and dissected; this is followed by removal of the diseased portion. B, A piece of ileum is brought through the colonic mesentery to bridge the renal pelvis and the bladder. C, Both proximal and distal anastomoses are completed in a full-thickness, watertight, tension-free manner.

techniques. The feasibility of the laparoscopic approach was affirmed in a more recent publication from [Stein and colleagues \(2009\)](#), which compared seven laparoscopic ileal ureters created during the same time period as seven open procedures. This retrospective comparison found analgesic use and time to convalescence to favor the laparoscopic approach (median morphine equivalents 38.9 vs. 322.2 mg, $P = .035$, and 4 vs. 5.5 weeks, $P = .03$, respectively). Although median follow-up was short, particularly in the laparoscopic cohort (13 months, range 2 to 79), the authors reported that all procedures were successful by both imaging and symptomatic measurements.

In addition, robotic-assisted laparoscopic ileal ureter has also been performed via a transperitoneal, four-port approach successfully ([Wagner et al, 2008](#)). Total operative time was 9 hours, with an acceptable hospital stay of 5 days.

Autotransplantation

In 1963 Hardy performed the first autotransplantation for a patient with proximal ureteral injury. Since then, clinical autotransplantation has been performed for a variety of problems including extensive ureteral loss or stricture ([Hardy, 1963](#); [Novick and Stewart, 1981](#); [Chuang et al, 1999](#); [Wotkowicz and Libertino, 2004](#)). In general, autotransplant is considered when the contralateral kidney is absent or poorly functioning or when other methods for ureteral substitution or repair are not feasible. The kidney is harvested with maximal vessel length as in a typical live donor nephrectomy for allotransplantation, and the renal vessels are anastomosed to the iliac vessels to reestablish renal perfusion. A healthy segment of the proximal ureter is anastomosed to the bladder ([Bodie et al, 1986](#)). Alternatively, the ipsilateral renal pelvis may be anastomosed directly to the bladder ([Kennelly et al, 1993](#)).

Not surprisingly, laparoscopy has been successfully incorporated in autotransplantation for severe ureteral loss. Nephrectomy can be performed laparoscopically as in any typical laparoscopic donor nephrectomy, followed by renal graft retrieval, bench preparation, and autotransplantation in the ipsilateral iliac fossa via a Gibson incision using the standard open surgical techniques ([Fabrizio et al, 2000](#); [Meng et al, 2003](#); [Blueblond-Langner et al, 2004](#)). The use of laparoscopy in autotransplantation has been shown to provide reduced postoperative analgesic need and faster recovery because a large open upper abdominal or flank incision for renal harvest is avoided. Laparoscopic nephrectomy in autotransplantation is most commonly performed transperitoneally. However, retroperitoneal approach for such purpose has been applied successfully by [Gill and colleagues \(2000b\)](#).

URETEROENTERIC ANASTOMOTIC STRICTURE

Incidence and Etiology

Several factors determine the incidence of stricture formation at the anastomosis of the ureter and intestine at the time of urinary diversion. The longest follow-up data available are for urinary conduits, in which the stricture rate is 4% to 8% and strictures are more common on the left ([Schmidt et al, 1973](#); [Skinner et al, 1980](#); [Mattei et al, 2008](#)). Factors potentially influencing outcome in this population include the technique used for ureteral dissection, the segment of bowel used for the diversion, and the type of anastomosis performed. Because ureteral ischemia is central to the cause of ureteroenteric strictures, careful attention to dissection is necessary to prevent complications.

The ureteral blood supply runs parallel to the ureter in the adventitia, and although ureteral mobilization is necessary to approximate the ureter and bowel and prevent tension on the anastomosis, stripping the ureter of its surrounding adventitia can lead to ureteral ischemia and stricture formation. The ileotomy technique is also a consideration. Cheng and associates reported using a shield-shaped ileotomy rather than a slit-shaped incision and found a 4.3% stricture rate compared with 8.3% in a retrospective assessment ([Cheng et al, 2011](#)). Barbieri and colleagues reported

KEY POINTS: SURGICAL REPAIR OF URETERAL STRICTURE

- Only short ureteral defects may be managed by end-to-end ureteroureterostomy.
- Distal ureteral stricture may be managed with ureteroneocystostomy with a psoas hitch or Boari flap.
- A Boari flap may be used to bridge a 10- to 15-cm ureteral defect. Small bladder capacity is a contraindication to such flap creation. Care should be taken to ensure adequate vascular supply to the flap.
- TUU is contraindicated in the presence of any disease process that may affect both ureters. It is also contraindicated if there is insufficient length of the donor ureter to reach the contralateral recipient ureter in a tension-free manner.
- Ileal ureter is useful in the presence of extensive ureteral loss. It is contraindicated in patients with baseline renal insufficiency with a serum creatinine of greater than 2 mg/dL, bladder dysfunction or outlet obstruction, inflammatory bowel disease, or radiation cystitis.
- Autotransplantation is considered when the contralateral kidney is absent or poorly functioning or when other methods for ureteral substitution or repair are not feasible.
- Laparoscopic or robotic reconstructive techniques in the hands of urologists skilled in these approaches may provide quicker recovery for patients.

ureteroileal anastomosis with intraluminal visualization in 118 patients with a 4.2% stricture rate at 15 months, all on the left side ([Barbieri et al, 2010](#)). With this approach the conduit is opened on the antimesenteric border to allow for direct visualization of the anastomosis. Moreover, Mattei and colleagues reported numerous advantages to routine stenting of ureteroileal anastomosis ([Mattei et al, 2008](#)). When performing an ileal conduit, the left ureter is brought underneath the sigmoid mesentery just overlying the aorta. The additional length and dissection needed on the left and the possibility of angulation around the inferior mesenteric artery may lead to a higher incidence of stricture formation on the left ([Mansson et al, 1989](#); [Barbieri et al, 2010](#)).

Controversy exists over the choice of bowel segment used for conduit diversion. One theoretic advantage to the use of colon is the feasibility of performing a nonrefluxing anastomosis. However, the reported incidence of renal deterioration with a nonrefluxing versus a refluxing ureterocolonic anastomosis has been mixed, and there does not appear to be a clear advantage with respect to renal function and colonization with a nonrefluxing anastomosis. The issues influencing stricture formation in continent urinary diversions become even more complex owing to the variety of bowel segments, reservoir configurations, and types of anastomoses available for reconstruction. The reported rate of ureteroenteric anastomotic stricture after continent diversion is 3% to 25%, with the majority occurring within the first 2 years ([Lugagne et al, 1997](#); [Weijerman et al, 1998](#); [Kouba et al, 2007](#)). Despite the paucity of randomized studies, there remains evidence in the literature that the risk of obstruction with a nonrefluxing anastomosis is significantly higher than that of a refluxing anastomosis. [Pantuck and colleagues \(2000\)](#) compared 60 nonrefluxing ureteroenteric anastomoses with 56 direct, refluxing anastomoses and found the long-term stricture rates to be 13% and 1.7%, respectively. With a mean follow-up of 41 months, there was no significant difference in the two groups with respect to hydronephrosis, pyelonephritis, nephrolithiasis, or renal insufficiency. Similarly, Roth and colleagues found a greater than fivefold increase in ureteral strictures in the group undergoing a nonrefluxing anastomosis ([Roth et al, 1996](#)). Their data also indicated that the risk of obstruction was unrelated to surgical expertise.

[Studer and colleagues \(1995\)](#) have reported a randomized study evaluating a nonrefluxing versus a refluxing anastomosis into an

isoperistaltic afferent ileal limb. Thirteen percent of nonrefluxing anastomoses resulted in stricture formation, as compared with 3% of refluxing anastomoses. Although there is no clear evidence that reflux into an adult kidney is detrimental, it is clear that obstruction is quite harmful to renal function. These studies and others support the use of a refluxing anastomosis in low-pressure continent reservoirs.

Kouba and colleagues compared the Wallace and Bricker techniques of ureteroileal anastomosis for continent and incontinent diversions and found low rates of stricture (0% to 3%) using both techniques in 186 patients with 34-month follow-up. Notably, with use of the Wallace technique (joined ureters) no strictures were identified, compared with 3.7% in patients undergoing the Bricker technique (separate ureters). Of note, the group undergoing the Bricker anastomosis had a higher BMI than the Wallace group (Kouba et al, 2007).

Evaluation

Screening of the upper tracts in patients who have undergone any type of urinary diversion may include renal ultrasound, CT, or MRI. If a stone or recurrent tumor is suggested, a CT scan or MRI is necessary for a more detailed assessment. In addition, patients with renal colic, recurrent urinary tract infection, or loss of renal function will require evaluation. In patients with hydronephrosis, CT urography, excretory urography, loopogram, or antegrade nephrostogram can provide information on the length and location of a stricture. Diuretic renography is indicated in patients with hydronephrosis to assess differential renal function and confirm the presence of functional obstruction. If hydronephrosis is present but renal function is insufficient for intravenous urogram or renography, placement of a nephrostomy tube and performance of an antegrade nephrostogram are both diagnostic and therapeutic. This approach is also useful before endoscopic intervention because it clarifies stricture length, which aids in surgical planning.

Indications for Intervention

Not all patients with urinary diversion and hydronephrosis require intervention. **Most patients with a long-term urinary conduit will have an element of chronic hydronephrosis that is not secondary to obstruction. In this population, a decrease in renal function or loss of reflux on a routine loopogram should prompt diuretic renography to quantitatively assess for functional obstruction.** Indications for intervention in patients with diversions and hydronephrosis include pain, infection, and renal insufficiency associated with functional obstruction. Although recurrence of transitional cell carcinoma at the level of the anastomosis is uncommon, the radiographic picture of an irregular mass at the level of the stricture and the rapid progression of obstruction and loss of renal function should prompt further evaluation and intervention (Tsuji et al, 1996).

A particularly challenging subset of patients is those undergoing urinary diversion as part of a pelvic exenteration for gynecologic malignancy. Penalver and colleagues (1998) reported on 66 patients, 95% of whom had undergone previous pelvic irradiation. Early and late complications at the ureteroenteric anastomosis were 22% and 10%, respectively. Eighty-five percent of the postoperative complications were managed successfully by conservative measures such as percutaneous nephrostomy.

Endourologic Management

Endourologic management of ureteroenteric strictures has evolved in a manner analogous to that for ureteral stricture disease. Although the initial procedures involved simple balloon dilation and stent placement, unsatisfactory results led to incisional techniques using electrocautery; more recently, the laser was applied using both fluoroscopic and direct endoscopic control. The current state-of-the-art incisional technique for endoureterotomy includes small-caliber flexible ureteroscopic instrumentation along with

holmium laser incision (Siegel et al, 1982; Muench et al, 1987; Cornud et al, 1992; Delvecchio et al, 2000; Laven et al, 2001, 2003; Schöndorf et al, 2013).

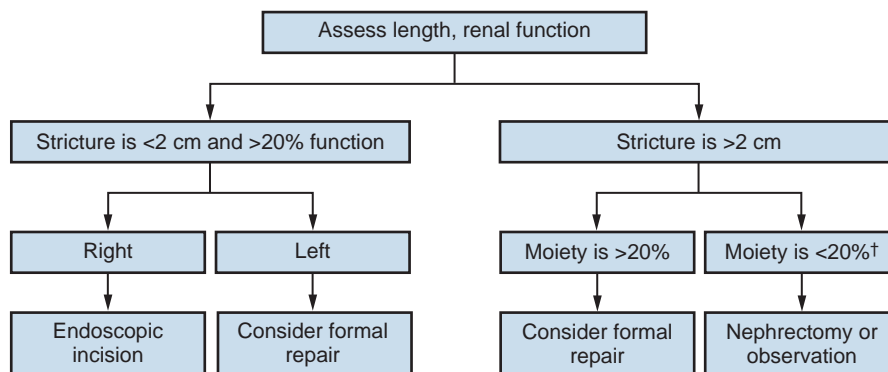

Endourologic management of ureteroenteric or ureterocolic strictures, unlike the management of ureteral strictures, still favors antegrade management. Accordingly, endourologic procedures typically begin with antegrade percutaneous access. Simple percutaneous drainage is continued to allow relief of any associated infection or obstruction-related renal dysfunction. Once the patient's condition is clinically stable, fluoroscopic control is used to pass a guidewire in an antegrade fashion across the anastomotic stricture, over which a balloon catheter can be positioned and inflated until the waist disappears. Stents are a routine part of endourologic management, and these are typically inserted in this same antegrade fashion. However, because of difficulty with mucous plugging of stents in this setting, many centers routinely use an internal-external stent, which can be easily flushed or changed over a wire. In addition, retrograde looposcopic access can be combined with percutaneous access and antegrade passage of a wire. With through-and-through control, the anastomosis can be visualized fluoroscopically or, preferably, with direct ureteroscopic, looposcopic, or trans-stomascopic visualization. Any number of procedures can then be used for the dilation itself including balloon dilation alone, electroincision with an electrode or hot-wire cutting balloon, or holmium laser incision. In all cases, a stent is placed, usually for 4 to 8 weeks.

Balloon dilation of ureteroenteric strictures was one of the first endourologic forms of management used, and fortunately long-term results are available. Notably, short-term reports of use of high-pressure balloon dilation have demonstrated success rates as high as 61% (Ravery et al, 1998). Alternatively, Shapiro and colleagues (1988) reported balloon dilation for 37 benign ureteroenteric strictures in 29 patients. Only 6 dilations (16%) were considered to have a successful result at least 1 year after interventional treatment, and repeat dilations were often required to maintain ureteral patency. Similarly, Kwak and colleagues (1995) achieved an overall success rate of less than 30% at 9 months for patients undergoing antegrade balloon dilation of ureteroenteric strictures. More recently, DiMarco and colleagues (2001) reported a 5% 3-year success rate in 52 balloon dilations of ureteroenteric anastomotic strictures. Recently Schöndorf and associates reported on 74 patients with ureteroenteric anastomotic strictures with a 26% success rate with endourologic intervention compared with a 91% success rate with open intervention at 29 months. **For strictures greater than 1 cm, the endourologic success rate was 6%, compared with a 50% success rate in strictures less than 1 cm. Endourologic intervention was successful 19% on the left compared with 41% on the right, whereas no difference was noted in sidedness with open repair (Schöndorf et al, 2013).**

Metallic stents have also been used for ureteroenteric anastomotic strictures, with acceptable short-term results. Overall, of 30 patients in the published literature, the reported patency rate is greater than 80% with 6- to 22-month follow-up (Kurzer and Leveillee, 2005). **There is a higher incidence of encrustation and stone formation with use of metallic stents for ureteroenteric anastomotic strictures, in addition to the risks of tissue ingrowth, recurrent obstruction, and stent migration (Kurzer and Leveillee, 2005; Gorin et al, 2011; Ng et al, 2013).** This may explain the limited published data regarding use of this approach.

Cautery wire balloon incision has also been reported in patients treated for ureteroenteric strictures (Lin et al, 1999; Schöndorf et al, 2013). For benign strictures, stent-free long-term patency was achieved in only 30% of patients. Meretyk and colleagues reviewed the long-term results of endourologic management of ureteroenteric anastomotic strictures at Washington University. In that study, 15 patients with 19 ureteroenteric strictures were followed for an average of 2.5 years. An antegrade approach was used most frequently and was usually combined with electroincision. A 57% long-term stent-free patency rate was achieved, even with follow-up longer than 2 years (Meretyk et al, 1991). **Whereas long-term patency of most endoscopic procedures approaches only 50%,**

OPTIMAL THERAPY FOR URETEROENTERIC ANASTOMOTIC STRICTURES*

*Consider balloon if transplant on immunosuppression.

†Pediatric patients and select patients with renal insufficiency may warrant repair.

Figure 49-34. Algorithm for management of ureteroenteric anastomotic stricture disease.

such approaches may be used preferentially as the initial intervention in select patients. Definitive operative management is reserved for patients in whom endourologic intervention fails and for patients with strictures longer than 1 cm (Kramolowsky et al, 1987, 1988; Schöndorf et al, 2013).

Cornud and associates (1996) reported their long-term results with percutaneous electroincision of ureterointestinal anastomotic strictures and specifically compared the results of fluoroscopic and endoscopic guidance. Twenty-seven patients were followed for longer than 1 year after stent removal, and an overall patency rate of 71% was reported. These investigators found better results when direct endoscopic control was combined with fluoroscopic guidance, compared with fluoroscopic guidance alone. In that report, right common iliac artery damage was reported during electroincision in 1 patient who had the procedure performed under fluoroscopic guidance alone. As a result, direct visual approaches have been favored for the management of ureteroenteric or ureterocolic anastomotic strictures, and the holmium laser has proven to be an excellent incisional tool. Endoureterotomy is typically performed in an antegrade manner, and success rates ranging from 50% to 80% have been reported (Singal et al, 1997; Laven et al, 2001; Watterson et al, 2002). These reports suggest the left side is more resistant to management because the majority of the failures occurred on the left side (Laven et al, 2003; Schöndorf et al, 2013). When considering endoscopic incision of a left ureteroenteric stricture, the risk of hemorrhage is a consideration because the sigmoid mesentery can be in close proximity. This, taken with the lower success rates of all endoscopic approaches on the left side, supports serious consideration for primary repair when treating left ureteroenteric anastomotic strictures (Fig. 49-34). In spite of this, Lovaco and colleagues reported good success treating 25 ureteroenteric strictures with endoureterotomy by an intraluminal invagination technique, with 80% success at more than 50 months' follow-up. Of note, this approach increases the distance between the incision site and surrounding vessels and viscera and does not favor left or right strictures (Lovaco et al, 2005).

RETROPERITONEAL FIBROSIS

Presentation and Etiology

RPF is typically characterized by the presence of an inflammatory, fibrotic process in the retroperitoneum causing compression of the retroperitoneal structures including the ureters. RPF most commonly affects patients who are 40 to 60 years of age. However, more than 30 cases of RPF have been reported in patients younger than 18 years of age (van Bommel, 2002). RPF cases have a male predominance, with a male-to-female ratio of 2:1 to 3:1. The true

KEY POINTS: URETEROENTERIC STRICTURES

- Although long-term patency of minimally invasive procedures for ureteroenteric strictures is in the range of 50%, such approaches are still used as the initial intervention, reserving operative management for those patients in whom endourologic intervention fails.
- When considering endoscopic incision of a left ureteroenteric anastomotic stricture in an ileal conduit, hemorrhage is a concern because the sigmoid mesentery can be in close proximity. Considering the low success rates of endoscopic approaches in this scenario, these patients may be best treated with definitive repair.
- Acceptable long-term success rates have been reported with open or robotic repair of ureteroenteric anastomotic strictures. As expected, strictures longer than 1 cm were more likely to recur and procedures on the left side had lower success rates.

incidence is unknown but has been estimated to be 1 per 200,000 to 500,000 per year.

In general, the retroperitoneal fibrotic mass centers around the distal aorta at L4 to L5 and wraps around the ureters, leading to hydronephrosis via extrinsic compression on the ureters or interference with ureteral peristalsis (Lepor and Walsh, 1979; Koep and Zuidema, 1987). In most patients, the presenting symptom is pain in the lower back and/or flank. The pain, which is typically dull, noncolicky, and unchanged with posture, may radiate to the lower abdomen or groin. Furthermore, the pain is often relieved by aspirin rather than narcotics. Other symptoms include weight loss, anorexia, nausea, generalized malaise, fever, hypertension, and oliguria or anuria. The mass may compress the inferior vena cava, resulting in deep venous thrombosis and lower extremity edema (Rhee et al, 1994). The mass may extend proximally to the renal hilum and encase the renal vein, resulting in renal vein hypertension and subsequent gross hematuria (Powell et al, 2000). Aortic obstruction and involvement of the mediastinum, the biliary system, the mesentery, and the kidney itself are rare (Tripodi et al, 1998; Azuma et al, 1999; Dejaco et al, 1999; Klisnick et al, 1999). Distal extension to the bifurcation of the iliac vessels may occur, and extension to the spermatic cord with scrotal involvement has been reported (Palmer and Rosenthal, 1999; Schulte-Baukloh et al, 1999). Duration of symptoms before diagnosis is usually 4 to 6 months, and approximately half of the patients have fibrosis that has caused significant ureteral obstruction and symptoms secondary to uremia.

In approximately 70% of patients, the disease is idiopathic. Currently, idiopathic RPF is considered part of the spectrum of chronic periaortitis, a large vessel vasculitis (Pipitone et al, 2012). Ceroid, a complex polymer of oxidized lipids and protein found in atherosclerotic plaques, has been suggested as the antigen initiating the inflammatory response (Parums et al, 1991). Indeed, a higher incidence of aortic aneurysms has been identified in patients with RPF (Breems et al, 2000). RPF usually occurs as an isolated disease entity, but it may occur as part of multifocal fibrosclerosis, a rare syndrome characterized by fibrosis involving multiple organ systems. In such a scenario, the clinical presentation may include RPF, sclerosing mediastinitis, sclerosing cholangitis, orbital pseudotumor, and Riedel thyroiditis (Dehner and Coffin, 1998; Özgen and Cila, 2000). The pathogenesis of these disorders is unknown but appears to be autoimmune in nature.

Among the 30% of RPF patients who have an identifiable cause, drugs such as methysergide (Sansert) and other ergot alkyls are most commonly associated with RPF. β -Blockers and phenacetin have also been implicated. The exact pathophysiology of drug-induced RPF remains unknown. Other causes of RPF include malignancies such as lymphoma, the most common malignancy in RPF cases, and multiple myeloma, carcinoid, pancreatic cancer, prostate cancer, and sarcoma (Webb and Dawson-Edwards, 1967; Usher et al, 1977). Radiotherapy for retroperitoneal malignancy is also known to produce a residual fibrotic mass leading to secondary ureteral obstruction. Asbestos exposure has also been associated with RPF in exposed workers in Finland, via gastrointestinal and pulmonary lymphatic drainage (Scheel and Feeley, 2013). In addition, infectious causes such as tuberculosis, *Actinomyces*, gonorrhea, and schistosomiasis have been suggested in the pathogenesis of RPF.

Association of RPF with membranous glomerulonephritis has also been documented in the literature (Mercadal et al, 2000; Shirota et al, 2002). The exact cause remains unclear, although the association has been speculated to be secondary to an unknown antigen triggering systemic immune response that leads to RPF. Association of RPF with ankylosing spondylitis and Wegener granulomatosis has also been reported, further suggesting an underlying immune cause in some patients (Izzedine et al, 2002; LeBlanc et al, 2002).

Pathologically, the typical gross appearance of RPF is that of a smooth, flat, tan-colored, dense mass enveloping the surrounding retroperitoneal structures. It is also known to invade the ureter or psoas muscle. Histologically, the appearance of RPF is that of a nonspecific inflammatory process that varies with the stage of the disease. Early in the disease, affected tissue consists mainly of collagen bundles with capillary proliferation and inflammatory cells including lymphocytes, plasma cells, and fibroblasts. In the later stage, the mass becomes relatively acellular and avascular, consisting of sheets of hypocellular collagen. RPF secondary to malignancy is often histologically indistinguishable from idiopathic RPF, and it can be identified only on the basis of the demonstration of small islands of tumor cells within the fibrotic mass.

Evaluation

In most RPF patients, the clinical symptoms are generally nonspecific, and physical examination is usually unrevealing. Laboratory evaluation may reveal an elevated erythrocyte sedimentation rate (ESR), elevated C-reactive protein (CRP), moderate leukocytosis, anemia, and variable renal insufficiency with associated electrolyte abnormalities. The ESR and CRP are elevated in one half to two thirds of patients with idiopathic RPF (Pipitone et al, 2012). If the overall renal function is normal, an excretory urogram or more commonly CT urography may be performed. Typical findings include hydronephrosis with medial deviation of the proximal ureter and mid-ureter and a smoothly tapered ureter at the level of obstruction. Urinary obstruction is usually bilateral, but unilateral cases have been described. Uncommonly, there are patients with symptoms of urinary obstruction but little hydronephrosis on imaging.

Figure 49-35. Typical computed tomographic findings of retroperitoneal fibrosis. The study demonstrates the presence of a homogeneous mass obliterating the outline of the great vessels at the lumbar area.

CT scan typically reveals hydronephrosis associated with a well-delineated retroperitoneal soft tissue mass enveloping the great vessels and the ureters (Fig. 49-35). If the patient has significant renal impairment, a retrograde pyelogram may be performed. In the radiographic evaluation of RPF, MRI can also be helpful because the mass itself has characteristic T1- and T2-weighted images. RPF is characterized as a diffusely low signal intensity on T1-weighted imaging, although the T2 signal may vary considerably, with high signal intensity consistent with active disease (Fig. 49-36). With treatment, T2 signal often diminishes and thus provides a measure of therapeutic efficacy. Moreover, gadolinium enhancement may also prove valuable in assessing the response to treatment because associated decreases in gadolinium contrast enhancement should also be expected after appropriate therapy (Cronin et al, 2008). Similarly, contrast enhancement on CT can also be used to monitor therapy, as can positron emission tomography (PET). In fact, PET appears to be the most sensitive imaging study for disease activity (Pipitone et al, 2012).

If a kidney is suspected to be nonfunctioning, differential renography should be considered to determine renal function because it may affect surgical planning. Representative biopsy samples of the mass should be obtained percutaneously or at the time of open or laparoscopic ureterolysis to rule out malignancy and allow one to proceed with treatment for RPF.

Management

Initial Management

The initial management of RPF depends on the patient's clinical status. Patients with hydronephrosis and uremia should be emergently decompressed by either percutaneous nephrostomy or indwelling ureteral stents. The advantages to placing ureteral stents include the opportunity to perform retrograde pyelograms to evaluate the anatomy and the convenience of internal drainage. It is interesting to note that ureteral stent placement is usually not difficult to perform in the setting of ureteral obstruction caused by RPF. In a critically ill patient with electrolyte abnormalities and little or no urine output, nephrostomy tube placement is favored. After renal decompression, the patient should be monitored closely for postobstructive diuresis, renal function status, and appropriate replacement of fluids and electrolytes.

After the initial management, an attempt to identify the cause of RPF should be made. Methysergide or any other potentially

Figure 49-36. A, T2-weighted magnetic resonance image of a symptomatic patient demonstrating retroperitoneal fibrosis with enhancement and thus active disease. B, Same patient after 1 month of medical therapy; note the decrease in enhancement on this corroborative T2-weighted image.

inciting drug, if identified, should be discontinued. Although most patients with malignant RPF have a prior history of malignancy, a thorough evaluation for occult malignancy with careful application of imaging studies is necessary. Biopsy to rule out malignancy, performed percutaneously or at the time of ureterolysis to provide long-term relief of obstruction, should be considered. However, some believe that in patients with no history of prior malignancy, no classic radiographic features on MRI or CT, and no lymphadenopathy, a biopsy is not essential before medical therapy.

Medical Management

Once the diagnosis of idiopathic RPF is made, the common primary medical management has been steroid therapy. In the medical literature there are approximately 170 cases of idiopathic RPF treated with steroids that resulted in about an 80% clinical response, including a decrease in size of the mass and improvement in ureteral obstruction or inferior vena cava compression (Kearney et al, 1976; Baker et al, 1987; Adam et al, 1998; Higgins et al, 1998; van Bommel, 2002; Fry et al, 2008). The characteristic clinical response to steroid therapy includes resolution of pain and constitutional symptoms within days after treatment, a rapid fall of ESR, and diuresis. Dose and duration of steroid therapy vary considerably in the literature, but most regimens start with initial doses of 60 mg daily tapered to 5 mg daily. Chronic steroid therapy up to 2 years has been shown to provide significant improvement in clinical symptoms and regression of retroperitoneal mass (Kardar et al, 2002), although relapse during tapering occurs in 25% to 50% of patients (Pipitone et al, 2012). Patients who have evidence of active inflammation—manifested by increased ESR, CRP, leukocytosis, or active inflammation on a biopsy—are more likely to respond to steroid therapy.

In addition to steroids, immunosuppressive agents including azathioprine, cyclophosphamide, cyclosporine, colchicine, and mycophenolate mofetil have been described to provide benefit in idiopathic RPF in isolated reports (Wagenknecht et al, 1981; McDougal et al, 1991; Grotz et al, 1998; Marzano et al, 2001; Vega et al, 2009). Medroxyprogesterone acetate, progesterone, and particularly tamoxifen have also been found to be beneficial in idiopathic RPF (Clark et al, 1991; Benson and Baum, 1993; Al-Musawi et al, 1998; Dedeoglu et al, 2000; Puce et al, 2000; Pipitone et al, 2012). The exact mechanisms of action of these medications are unclear, but they are believed to inhibit fibroblastic proliferation leading to clinical response. Use of immunosuppressive agents is reserved for patients in whom steroid therapy fails, because relapses are as high as 50% during steroid tapering (Pipitone et al, 2012).

Surgical Management: Open Ureterolysis

Ureterolysis may be performed open surgically or laparoscopically, although open surgery has been considered the standard (Lindell and Lehtonen, 1988; Elashry et al, 1996). It is performed with concomitant biopsy of the mass in patients with an unclear diagnosis as the definitive initial treatment or in those in whom medical therapy has failed. When open surgery is performed, a midline, transperitoneal abdominal incision is made to allow access to both ureters. Placement of ureteral catheters or stents before the abdominal incision is advisable to assist identification and dissection of the ureters. Although hydronephrosis may be unilateral on preoperative assessment, the process in general is bilateral, requiring bilateral ureterolysis. After medial mobilization of the ascending and descending colon, deep biopsies of the mass should be performed for frozen and permanent section to rule out malignancy. Dissection should begin at the distal, nondilated ureteral segment to avoid injury to the thin, dilated proximal segment. A right-angle clamp can be placed between the ureter and the retroperitoneal mass along the course of the ureter, and the fibrotic tissue is then incised above the clamp. This is repeated throughout the length of the entrapped ureter, using both blunt and sharp dissection techniques to free the affected ureter from its fibrous bed. The ureteral wall may become quite thin at times following the dissection. An inadvertent ureterotomy should be closed with absorbable suture. Ureteral excision with ureteroureterostomy is usually unnecessary.

After bilateral ureterolysis, the ureters should be repositioned and protected from further fibrous entrapment. Several surgical options are available. One option is to retract the ureters laterally and secure the overlying peritoneum medially to the psoas muscle to maintain the ureters in this location. Another option is to close the peritoneum behind the ureters so that the ureters may be displaced anteriorly into the peritoneal cavity (Tresidder et al, 1972). It is important not to obstruct the ureter in the closure of the peritoneum at the ureteral hiatus. In a report on a group of patients with idiopathic RPF undergoing intraperitoneal placement of the ureters or lateral retroperitoneal placement of the ureters, no difference in the radiologic or clinical outcome was found (Barbalias and Liatsikos, 1999). In the setting of extensive RPF, a more definitive approach is to surround the ureters with omentum and reposition them within the peritoneal cavity (Carini et al, 1982). For the omental wrap to be performed, the omentum is first mobilized from its attachment to the transverse colon, followed by its division along its midline with ligation of the small omental vessels up to the gastric attachment. The short gastric vessels are then divided and ligated at the level of the stomach wall, after which the two halves of the omentum can be retracted

Figure 49-37. A, Preoperative intravenous contrast-enhanced radiograph of a patient with idiopathic retroperitoneal fibrosis, showing bilateral hydronephrosis with medial deviation of the ureters. B, Postoperative radiograph of the same patient after surgical ureterolysis with intraperitoneal omental wrapping.

laterally on the basis of the right and left gastroepiploic arteries. The entire length of the ureter can be surrounded by omental tissue, which is tacked in place with absorbable sutures (Fig. 49-37). The omentum provides protection of the ureter against recurrent extrinsic compression and vascularity to a potentially ischemic ureter. Steroid therapy may be used postoperatively in an attempt to prevent recurrent upper tract and venous compression. If no ureterotomy occurs during ureterolysis, the previously placed stents may be removed shortly after surgery.

If ureterolysis is impossible to perform owing to extensive periureteral fibrosis, renal autotransplantation may be performed if the ipsilateral renal unit demonstrates satisfactory function (Penalver et al, 2001). If no significant renal function can be recovered after an adequate time period of decompression in the presence of the satisfactory contralateral renal function, nephrectomy may be considered.

Surgical Management: Laparoscopic Ureterolysis

The first laparoscopic ureterolysis was reported by Kavoussi and Clayman in 1992 (Kavoussi et al, 1992). Subsequent success with such technique was confirmed by others (Puppo et al, 1994). Another report described experience with laparoscopic ureterolysis in 13 patients including bilateral procedures in 7 and unilateral procedures in 6 (Fugita et al, 2001). Preoperative stent placement was performed in all patients before laparoscopy. For each ureter, the laparoscopic procedure was performed using a transperitoneal four-port approach. After incision of the posterior peritoneum and mobilization of the colon, the affected ureter was dissected free from the retroperitoneal fibrotic tissue. Multiple frozen-section biopsy specimens of the periureteral tissue were obtained to rule out malignancy. The edge of the posterior peritoneum was reapproximated to the sidewall underneath the ureter to intraperitonealize the ureter. Laparoscopic ureterolysis was completed successfully

in 85% (11) of the cases, with 2 (15%) open conversions because of iliac vein injury (in one patient) and marked fibrosis (in one patient). Mean operative time was 381 minutes for bilateral procedures and 192 minutes for unilateral procedures. Mean use of parenteral analgesics was 59 mg of morphine sulfate equivalent. Mean hospital stay was 4 days. Postoperative complications occurred in 30% (4) of the patients and included epididymitis, umbilical port erythema, prolonged ileus, and urinary retention. Pathology showed fibrous tissue with lymphocytes, plasma cells, macrophages, and fibroblast proliferation in all patients. At a mean follow-up of 30 months, upper tract imaging such as intravenous urography or renal scan showed lack of obstruction in 92% (12) of the patients. A multi-institutional survey that included 17 academic centers identified that centers with a fellowship-trained laparoscopist performed laparoscopic ureterolysis, and in 59% of centers urologists performed the medical management. Notably in this survey, the reported laparoscopic success rates were 83% (Duchene et al, 2007).

A more recent retrospective comparison of laparoscopic and open ureterolysis (16 ureters in each group) concluded that the minimally invasive approach was associated with a shorter hospital stay (mean 2.1 vs. 5.9 days, $P = .004$) but that success and complication rates were similar with both approaches (Styn et al, 2011).

Robotic ureterolysis for RPF has also been reported. Keehn and colleagues (2011) treated a total of 21 renal units in 17 patients with robotic ureterolysis and omental wrapping. Fourteen percent recurred and required a secondary surgical intervention, whereas 86% remain patent at a mean follow-up of 20.5 months. The researchers reported one perioperative complication, an enterocutaneous fistula from an unrecognized thermal bowel injury that required bowel resection.

KEY POINTS: RETROPERITONEAL FIBROSIS

- In general, the retroperitoneal fibrotic mass centers around the distal aorta at L4 to L5 and wraps around the ureters, leading to hydronephrosis via extrinsic compression on the ureters or interference with ureteral peristalsis. In most cases the disease is idiopathic, associated with chronic aortitis.
- RPF symptoms and signs are usually nonspecific. Laboratory evaluation may show an elevated ESR, CRP, moderate leukocytosis, anemia, and variable renal insufficiency associated with electrolyte abnormalities.
- Initial management of RPF in the presence of hydronephrosis and uremia includes emergent decompression by percutaneous nephrostomy or indwelling ureteral stents. After decompression, the patient should be monitored closely for postobstructive diuresis.
- The most common primary medical management of idiopathic RPF has been steroid therapy, with immunosuppressive agents as second line.
- In surgical bilateral ureterolysis, the ureters need to be protected by intraperitonealization or omental wrapping. Both open and laparoscopic techniques may be applied successfully. If ureterolysis is impossible to perform, renal autotransplantation may be performed.

Renal Injuries

RENAL INJURIES

The kidneys are the most commonly injured genitourinary organs from external trauma. Advances in radiographic staging, improvements in hemodynamic monitoring, and wider use of angioembolization have improved the rates of renal preservation and decreased unnecessary surgery. **The majority of blunt and many penetrating injuries to the kidneys no longer require open surgical intervention.** Close follow-up of these patients and timely treatment of nonoperative failures or complications are still mandatory.

Presentation and History

Motor vehicle accidents, falls from heights, and assaults contribute to the majority of blunt renal trauma. Direct transmission of kinetic energy and rapid deceleration forces place the kidneys at risk. **Perhaps the most important information to obtain in the history of blunt renal injury is the extent of deceleration involved in high-velocity impact trauma.** Significant acceleration/deceleration can cause rare but lethal renovascular injuries. These occur when the kidney tears at retroperitoneal points of fixation such as the renal hilum or ureteropelvic junction, resulting in renal artery thrombosis, renal vein disruption, and renal pedicle avulsion. A more specific history of injury mechanism can be helpful. For example, the majority of the renal injuries after automobile accidents were caused by unrestrained drivers with direct impact on the steering wheel or side impact with the lateral door, often with 30 cm or more of door incursion (Kuan et al, 2007). Understanding details of the accident from first responders at the scene can increase the level of suspicion for renal injury.

Penetrating renal injuries most often come from gunshot and stab wounds. Gunshot wounds comprise the great majority of the penetrating trauma, with stab wounds a distant second (86% vs. 14%). Penetrating mechanisms lead to higher rates of significant and persistent renal bleeding, need for renorrhaphy/nephrectomy, and complications when managed nonoperatively. Of all patients sustaining renal trauma in a large urban series, renal gunshot wounds occurred in approximately 4% (McAninch et al, 1993).

Stab wounds from assault or self-inflicted injuries can cause both renovascular and parenchymal injuries. Common entry sites including the upper abdomen, flank, and lower chest should alert the clinician to possible renal involvement. **Trauma to the anterior axillary line is more prone to damage important renal structures such as the renal hilum and pedicle compared to the posterior axillary line, which more commonly results in parenchymal injury.** Should the weapon be recovered, its dimensions should be noted because the length and width give valuable information on its penetrating and destructive characteristics.

Physical examination of all body systems must be detailed and complete. In a conscious patient, a thorough history can be taken during the examination. Rapid resuscitation according to American Association for the Surgery of Trauma (AAST) guidelines should be followed for polytrauma. With a blunt mechanism, cervical spine

Ureteral Injuries

immobilization is mandated until confirmed intact by radiography. Examination of the abdomen, chest, and back must be performed. The presence of a flank hematoma, abdominal or flank tenderness, rib fractures, and penetrating injuries to the low thorax or flank indicate possible renal injury. **Ipsilateral rib fracture can increase the incidence of significant renal trauma threefold.**

Gunshot injuries can be misleading in that small entrance wounds may underestimate larger tissue destruction within the body. Exit wounds are frequently, but not necessarily, much larger. Soft tissue and bone can alter the bullet's trajectory; thus the projectile may not take a direct path from entrance to exit. Bullet fragments can create secondary missiles, resulting in multiple injury tracts. When radiographs of the chest and abdomen are taken, it is useful to place a small metallic object at entrance and exit sites to help define these locations on the films.

Hematuria

The best indicators of significant urinary system injury include gross and microscopic hematuria (>5 red blood cells/high-power field [RBCs/HPF] or positive dipstick finding), especially when associated with acceleration/deceleration injury, penetrating trauma, or hypotension in the field or emergency room (systolic blood pressure <90 mm Hg).

The degree of hematuria and the severity of the renal injury do not consistently correlate. Gross hematuria has been observed in minor renal contusions, and microscopic hematuria has been seen in some with severe renal injuries. Hematuria was absent in 7% of 420 grade IV renal injuries in a recent analysis (Shariat et al, 2008a), and 36% of renal vascular injuries from blunt trauma demonstrated no blood in the urine (Cass, 1989). Also, approximately 50% of injuries to the ureteropelvic junction have no microscopic or gross hematuria. In patients with blunt trauma, microscopic hematuria associated with shock significantly increases the incidence of severe renal injuries (Nicolaisen et al, 1985; Mee and McAninch, 1989; Mee et al, 1989; Miller and McAninch, 1995).

The first aliquot of urine obtained by catheterization or voiding is used to determine the presence of hematuria. Later urine samples may be diluted by diuresis from resuscitation fluids, resulting in an underestimation or absence of hematuria. Any degree of visible blood in the urine is regarded as gross hematuria. Microscopic hematuria can be detected by dipstick analysis or microanalysis. The dipstick method is rapid and has a sensitivity and specificity for detection of microhematuria of more than 97%, even though a poor correlation with actual urinalysis was noted in a single study (Chandhoke and McAninch, 1988). **Although critical to the initial evaluation of traumatic urinary tract injury, the presence or absence of hematuria should not be the sole determinant in the assessment of a patient with suspected renal trauma.** Because the significance of hematuria varies with blunt and penetrating mechanisms, the importance of proper detection and staging of renal injuries, usually by computed tomography (CT), must be emphasized.

Classification

The AAST Organ Injury Scaling Committee (Moore et al, 1989) provides the most widely used and accepted classification of renal injury (Table 50-1, Fig. 50-1). Based on accurate grading made possible by contrast-enhanced CT, the AAST injury severity scale is a powerful and valid predictive tool for clinical outcomes in patients with renal trauma (Santucci et al, 2001).

Indications for Renal Imaging

The criteria for radiographic imaging include the following:

1. All penetrating trauma with a likelihood of renal injury (abdomen, flank, or low chest entry/exit wound) who are hemodynamically stable enough to have a CT (instead of going right to the operating room or angiography suite)

2. All blunt trauma with significant acceleration/deceleration mechanism of injury, specifically rapid deceleration as would occur in a high-speed motor vehicle accident or a fall from heights
3. All blunt trauma with gross hematuria
4. All blunt trauma with microhematuria and hypotension (defined as a systolic pressure of less than 90 mm Hg at any time during evaluation and resuscitation)
5. All pediatric patients with greater than 5 RBCs/HPF

An extensive prospective study based at San Francisco General Hospital evaluating indications for radiographic imaging was ongoing for more than 25 years. The findings have been updated on three reports (Nicolaisen et al, 1985; Mee and McAninch, 1989; Miller and McAninch, 1995) (Fig. 50-2). Based on information from this study, all patients with blunt trauma with gross hematuria and patients with microscopic hematuria and shock (systolic

TABLE 50-1 American Association for the Surgery of Trauma Organ Injury Severity Scale for the Kidney

GRADE*	TYPE	DESCRIPTION
I	Contusion Hematoma	Microscopic or gross hematuria, urologic studies normal Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma Laceration	Nonexpanding perirenal hematoma confined to renal retroperitoneum <1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	>1 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration Vascular	Parenchymal laceration extending through renal cortex, medulla, and collecting system Main renal artery or vein injury with contained hemorrhage
V	Laceration Vascular	Completely shattered kidney Avulsion of renal hilum, devascularizing the kidney

*Advance one grade for bilateral injuries up to grade III.

Data from Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. J Trauma 1989;29:1664-6.

Figure 50-1. Classification of renal injuries by grade (based on the organ injury scale of the American Association for the Surgery of Trauma [based on Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. J Trauma 1989;29:1664-6.]).

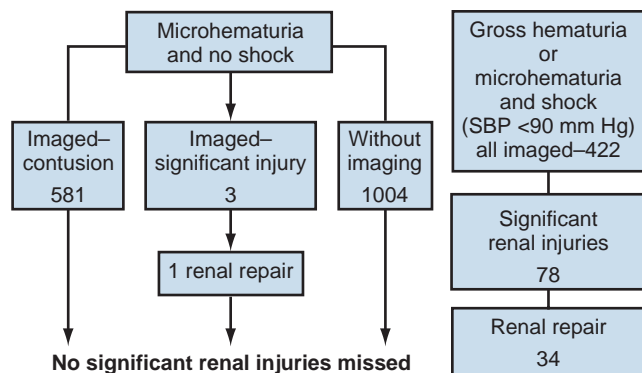

Figure 50-2. Algorithm demonstrating the results of the authors' study on radiographic assessment of renal injuries. In adults with blunt trauma, imaging studies may be performed selectively. SBP, systolic blood pressure. (From Miller KS, McAninch JW. Radiographic assessment of renal trauma: our 15-year experience. *J Urol* 1995;154:352–5.)

blood pressure < 90 mm Hg any time during evaluation and resuscitation) should undergo renal imaging, usually with CT using intravenous (IV) contrast and with delayed films to evaluate urinary extravasation.

Patients with microscopic hematuria without hypotension or acceleration/deceleration injury can be observed clinically without imaging. First noted by Miller and McAninch (1995) but confirmed by several subsequent findings, these patients rarely have a significant injury (<0.0016%). However, if renal injury is suspected on the basis of history, examination, or the patient's subsequent clinical course, imaging should be performed. It is important to remember that blunt rapid deceleration injuries, such as high-speed motor vehicle accidents or falls from great heights, pose a higher risk for vascular pedicle or ureteral injury.

Penetrating injuries with any degree of hematuria should be imaged. In a report by Carroll and McAninch (1985), 27 of 50 patients with penetrating renal trauma had only microscopic hematuria. Three of these had practically undetectable amounts of microhematuria—0 to 3 RBCs/HPF. Despite this, one of the three had a renal pedicle injury.

Pediatric patients (younger than 18 years) sustaining blunt renal trauma generally can be evaluated like adults (Santucci et al, 2004a), with a few caveats:

1. Children are known to be at a greater risk for renal trauma than adults after blunt abdominal injury (Brown et al, 1998a) perhaps because of larger comparative kidney size and less relative rib coverage over the kidneys (Buckley and McAninch, 2004).
2. Importantly, children often do not become hypotensive with major blood loss, and in the absence of this sign can still have significant exsanguinating renal injury. Liberal use of renal imaging is probably warranted. Children have a high catecholamine output after trauma, which maintains blood pressure until approximately 50% of blood volume has been lost.
3. Children have a higher proportion of renal abnormalities such as severe hydronephrosis or Wilms tumor, which may result in significant renal injury with seemingly insignificant renal trauma.

Imaging Studies

Contrast-enhanced CT is the gold standard for genitourinary imaging in renal trauma (Bretan et al, 1986; Federle et al, 1987). Quick, highly sensitive, and specific, CT provides the most definitive staging information—parenchymal lacerations are clearly defined; extravasation of contrast-enhanced urine can easily be detected (Fig. 50-3); associated injuries to the bowel, pancreas, liver, spleen, and other organs can be identified; and the degree of retroperitoneal bleeding can be assessed by the size of the retroperitoneal hematoma. Lack of uptake of contrast material in the parenchyma

Figure 50-3. Computed tomography scan of a right renal stab wound (grade IV) (arrow), demonstrating extensive urinary extravasation and large retroperitoneal hematoma.

suggests arterial thrombosis (Fig. 50-4) or transection. Detection of fine anatomic detail of the most serious injuries (urinary extravasation, active arterial bleeding, and severe parenchymal/vascular injuries) has translated into improved confidence in our ability to understand which injuries can be managed nonoperatively.

Currently, spiral CT is being used in many centers to evaluate renal injuries (Brown et al, 1998b). Arteriovenous scanning (typically 80 seconds after contrast administration) provides visualization of the kidneys in the nephrogenic phase of contrast excretion and is necessary to detect arterial extravasation. Injury to the renal collecting system may be missed if contrast material has not had time to be excreted into the parenchyma and collecting system adequately. Repeated/delayed scanning of the kidneys 10 minutes after injection of contrast identifies parenchymal lacerations and urinary extravasation accurately and reliably. Expert opinion holds that delayed films may be omitted when the kidneys are deemed normal, and no perinephric, retroperitoneal, pelvic, or perivesical fluid is present (Santucci et al, 2004b). Findings on CT that raise suspicion for major injury are (1) medial hematoma, suggesting vascular injury; (2) medial urinary extravasation, suggesting renal pelvis or ureteropelvic junction avulsion injury; (3) global lack of contrast enhancement of the parenchyma, suggesting renal artery occlusion; and (4) the combination of two or more of the following: large hematoma greater than 3.5 cm, medial renal laceration, and vascular contrast extravasation (suggesting brisk active bleeding).

Patients with two or three of these last features (no. 4 in the previous list) require open surgery or angioembolization nine times more frequently than those with none or one of these features (Dugi et al, 2010). Also, active extravasation of intravascular contrast seen on CT (i.e., the patients are bleeding so briskly as to be detectable on the vascular phase CT scan) is highly associated with the need for subsequent angioembolization (Nuss et al, 2009) (Fig. 50-5). The widespread use and anatomic detail provided by CT imaging has now supplanted the much less sensitive and less specific excretory urography (IV pyelography [IVP]) for grading purposes.

One major limitation of CT is the inability to define a renal venous injury adequately. With normal arterial perfusion, the parenchyma appears normal and the collecting system may contain contrast material. A medial hematoma accompanying the preceding findings suggests a venous injury. Most venous injuries will either bleed so much they will have to go to the operating room or tamponade and stop bleeding and thus require no further treatment. The true clinical significance of the insensitivity of CT to renal vein injury is currently unknown.

Figure 50-5. Computed tomography showing left renal fossa hematoma after blunt renal trauma, with bright jet of active extravasation of intravascular contrast indicating brisk active bleeding.

There is a limited continuing role for intraoperative “one-shot” IVP. The indications are uncommon, but when the surgeon encounters an unexpected retroperitoneal hematoma surrounding a kidney during abdominal exploration in a patient without a previous CT scan, the study can provide essential information. The main purpose of the one-shot IVP is to assess the presence of a functioning contralateral kidney and help radiographically stage the injured side. It is crucially important to know if a patient has only one kidney, because any unnecessary attempts at repair that might endanger that remaining kidney must be avoided. The IVP technique is key to gaining important information and minimizing the time involved; only a single film is taken 10 minutes after IV injection (IV push) of 2 mL/kg of contrast material. The study is particularly helpful in determining whether urinary extravasation is present. If the study is normal, exploration of the injured side may be avoided. If findings are not normal or near normal, the kidney should be explored to complete the staging of the injury and reconstruct any abnormality found.

Morey and coworkers (1999) reported their experience with one-shot intraoperative IVP for the immediate management of renal injuries; in 50 patients the film quality was adequate to avoid renal

exploration in 32%. This report supports the value of this intraoperative imaging technique when done properly.

Sonography is used in the immediate evaluation of abdominal injuries (focused assessment with sonography for trauma [FAST] examination), but the study has poor specificity in the adult renal patient for renal injuries. If necessary, sonography can confirm the presence of two kidneys and can detect a retroperitoneal hematoma.

Angioembolization

Renal arteriography and embolization is an increasingly used modality in renal trauma. In the right setting, it can be used to stop significant renal bleeding without the need for laparotomy. Most angiography literature consists of case reports and a single report of patients found in an administrative database; however, it appears to be commonly used clinically. It is critically important that if angioembolization is used, the local angiography team is experienced, the procedure can be done without delay, and that the patient can be monitored and even resuscitated during transport to and in the angiography suite. Superselective embolization therapy for renal trauma may provide an effective and less invasive technique to avoid unnecessary exploration that could otherwise result in a nephrectomy. Initial failure is common, between 13% and 88% (Breyer et al, 2008; Sugihara et al, 2012), but subsequent embolization was highly successful in at least one series (Hotelling et al, 2011).

Traumatic pseudoaneurysms and arteriovenous fistulas are often treated by angiographic embolization with a high expected success rate (Fig. 50-6). In special clinical circumstances, endovascular stents have been used with reported success during angiography in patients with renal artery thrombosis occurring from intimal flaps (Goodman et al, 1998). Longer term follow-up and more cases are needed to determine whether this will be a successful management approach, especially considering that most stents require anticoagulation after placement, which may not be possible in a trauma patient.

Nonoperative Management

Significant renal injuries (grades II to V) are found in only 5% of renal trauma cases (Miller and McAninch, 1995). Nonoperative management has become the standard of care in hemodynamically stable, well-staged patients with AAST grade I to III renal injuries, regardless of mechanism (Santucci et al, 2004b). Most

Figure 50-6. A, Computed tomography showing left post-traumatic arteriovenous fistula. B, Angiogram showing left post-traumatic arteriovenous fistula. C, Angioembolization of right renal laceration: arteriography demonstrating active arterial bleeding. Coil embolization was used to control bleeding. Note the presence of the coil and large, triangular area of infarct.

experts agree that patients with grade IV and V injuries more often require surgical exploration, but even these high-grade injuries can be managed without renal operation if carefully staged and selected (Fig. 50-7) (Santucci and McAninch, 2000; Santucci et al, 2004b; Buckley and McAninch 2006; Umbreit et al, 2009; Van der Wilden et al, 2013).

A trial of expectant management has been advocated for most adult blunt renal parenchymal injuries, many renal stab wounds, and selected renal gunshot wounds. Bluntly injured kidneys often heal well when managed conservatively, even in the setting of urinary extravasation and nonviable tissue. Overall, 98% can be successfully managed without exploration. Even very high-grade injuries can sometimes be treated nonoperatively. In a series of six hemodynamically stable, grade V blunt injuries, all were treated successfully without surgery (Altman et al, 2000). Patients who are exsanguinating from the kidney may still require exploration and subsequent nephrectomy/renorrhaphy, but those who are hemodynamically stable are often successfully treated without surgery (Moolman et al, 2012). Delayed bleeding, usually amenable to angioembolization, occurs in 9%.

Penetrating trauma from gunshot or stab wounds to the kidney also can be managed nonoperatively in stable patients. In one large series, 55% of renal stab wounds and 24% of gunshot wounds were appropriately managed nonoperatively in carefully selected patients with well-staged injuries (McAninch et al, 1991). Contrary to past teaching, obligatory exploration is no longer mandated for renal gunshot wounds. Serafetinides and associates (2004) treated 40 patients (54%) with low-velocity gunshot wounds expectantly with few complications.

Stab injuries have even more evidence to support conservative management. Nonoperative management was successful and resulted in no delayed nephrectomies in a cohort of 108 hemodynamically stable patients with stab wound (Armenakas et al, 1999).

Some blunt and penetrating abdominal trauma may require laparotomy because of associated nonurologic injury, but even in these cases it is not necessary to explore the kidney additionally (Shariat et al, 2008b). The only absolute indication for kidney exploration is a pulsatile and expanding retroperitoneal hematoma that suggests renal artery laceration. This is a vanishingly rare clinical entity.

All patients with high-grade injuries selected for nonoperative management should be closely observed with serial hematocrit readings and vital signs. Supporting data are lacking, but we empirically prescribe bed rest until gross hematuria resolves. **No routine CT imaging is required in patients without symptoms (fever, flank pain, dropping hematocrit, increasing hematuria, etc.)** (Davis et al, 2010). Although most grade II to IV injuries resolve uneventfully, delayed renal bleeding sometimes can occur (Wessells et al, 1997). Should bleeding persist or delayed bleeding occur, angiography with selective embolization of bleeding vessels can obviate surgical intervention. The patient should be watched and warned about the possibility of acute or delayed renovascular hypertension. Delayed bleeding after discharge to home is rare but does occur.

The failure rate of nonoperative management is as high as 20% (average ~ 10%), but most patients require only a stent or angioembolization. The complication rate of nonoperative treatment is much lower than that of aggressive surgical exploration and results in shorter intensive care unit (ICU) stays, shorter hospital stays, lower mortality, and fewer transfusions (Bjurlin et al, 2011). However, it cannot be overemphasized that patients who are exsanguinating from the kidney require rapid open surgical or in some cases quick expert angioembolization to avoid death.

In severe renal injuries with continued urinary extravasation, placement of an internal ureteral stent for drainage may prevent prolonged urinary extravasation and decrease the chance of perirenal urinoma formation. On occasion, retrograde placement of

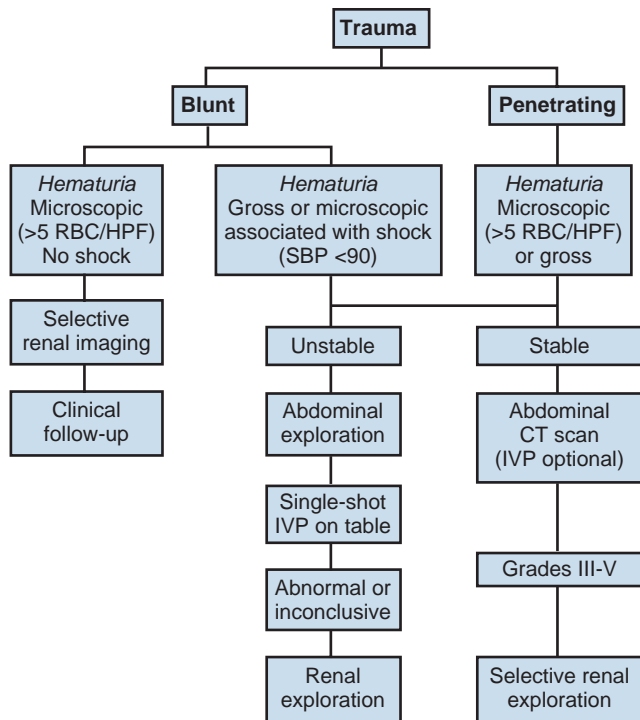

Figure 50-7. Flow chart for adult renal injuries to serve as a guide for decision making. CT, computed tomography; IVP, intravenous pyelography; RBC/HPF, red blood cells per high-power field; SBP, systolic blood pressure.

ureteral stents is not possible. Examples include concomitant pelvic fracture urethral distraction defects, severe genital trauma prohibiting urethral access, complete ureteral transection, and fractures prohibiting the dorsal lithotomy position. Percutaneous nephrostomy drainage with consideration for antegrade ureteral stent placement is a viable option in these situations. Stenting and draining will facilitate renal healing.

Fluid collections seen on serial imaging for renal trauma are hematomas, urinomas, or abscesses. Urinomas can be distinguished from hematomas by their radiographic characteristics. Urinoma density in Hounsfield units (HU) ranges from 0 to 20; hematoma density is almost always greater than 30 (Federle and Jeffrey, 1983). Also, urinomas enhance with contrast pooling dependently during delayed phase imaging (5 to 20 minutes after IV injection of contrast). Abscesses have rim enhancement and high attenuation fluid (HU > 20) on contrasted films (Allen et al, 2012). When the perinephric fluid collection persists despite ureteral stenting or percutaneous nephrostomy drainage, placement of a percutaneous drain can facilitate healing and prevent or treat abscesses.

Operative Management

Indications for renal exploration or speedy angioembolization after trauma can be separated into absolute and relative (Voelzke and McAninch, 2008). Absolute indications include (1) hemodynamic instability with shock, (2) expanding/pulsatile renal hematoma (usually indicating renal artery laceration), (3) suspected renal vascular pedicle avulsion (grade 5), and (4) ureteropelvic junction disruption. Relative indications are (1) urinary extravasation with significant renal parenchymal devascularization (older data suggest higher complication rate than average if watched, but these also can be closely observed), (2) renal injury together with colon/pancreatic injury (these patients have a higher complication rate if their renal injury is not repaired at the time of colon/pancreatic injury, but the renal injury may be closely observed after repair of the enteric injury), and (3) a delayed diagnosis of arterial injury (which will most likely need delayed nephrec-

tomy). More recent data suggest that patients with renal devascularization and urine leak actually have excellent outcomes, with only 1 of 18 (6%) patients requiring subsequent intervention during conservative management of segmental renal artery injuries (Elliott et al, 2007).

Urinary extravasation alone from a grade IV parenchymal laceration or fornical rupture can be managed nonoperatively with an expectation of spontaneous resolution of more than 90%. Should nonviable tissue constitute more than 25% in association with a parenchymal laceration, urinary extravasation, or both, the potential for complications greatly increases and operative management may be considered (Alsikafi et al, 2006).

Renal Exploration

Surgical exploration of the acutely injured kidney is best done by a transabdominal approach, which allows complete inspection of intra-abdominal organs and bowel. In some reported series of penetrating injuries, nonrenal organ injury has been noted to be as high as 94% (McAninch et al, 1993). Injuries to the great vessels, liver, spleen, pancreas, and bowel can be identified and stabilized, if necessary, before renal exploration.

The surgical approach to renal exploration is shown in Figure 50-8 (McAninch and Carroll, 1989). The renal vessels are isolated before exploration to provide the immediate capability to occlude them if massive bleeding should ensue when the Gerota fascia is opened (Scott and Selzman, 1966). The small bowel is eviscerated and lifted out of the surgical field. This exposes the mid-retroperitoneum. An incision is made over the aorta in the retroperitoneum just superior to the inferior mesenteric artery. The incision is extended superiorly to the ligament of Treitz. Exposure of the anterior surface of the aorta is accomplished and followed superiorly to the left renal vein, which crosses the aorta anteriorly. A vessel loop is placed on the right or left renal vein as necessary. The vein usually must be retracted cephalad, perhaps with a Deaver retractor, and the left and right renal arteries will be found underneath. The artery is secured with vessel loops. The right renal vein also can be secured through this incision; but if this proves difficult, reflecting the second portion of the duodenum provides excellent exposure to the vein.

Large hematomas may extend over the aorta and obscure the landmarks for the planned initial retroperitoneal incision. In such instances, the inferior mesenteric vein can be used as an anatomic guide for an appropriate incision. By making the retroperitoneal incision just medial to the inferior mesenteric vein and dissecting through the hematoma, the anterior surface of the aorta can be identified and followed superiorly to the crossing left renal vein.

The kidney is then exposed by incising the peritoneum lateral to the colon, followed by mobilization off the Gerota fascia. This maneuver often requires release of the splenic (left) or hepatic (right) attachments of the colon. The Gerota fascia is then opened, and the kidney with injury is completely dissected from the surrounding hematoma. Should troublesome bleeding develop, the previously isolated vessels can be temporarily occluded with a vascular clamp or a vessel loop tourniquet.

Is Early Vessel Isolation Necessary? Renal bleeding is a major cause of nephrectomy in renal trauma. Obtaining early vascular control before opening the Gerota fascia can decrease renal loss; in a comparative series, the total nephrectomy rate was reduced from 56% to 18% when vascular control was obtained (McAninch and Carroll, 1982). Carroll and coworkers (1989) reported that the looped vessels only needed to be temporarily clamped in approximately 2% of renal explorations. In a series of 133 renal units in which early vessel isolation and control were achieved before opening the Gerota fascia, McAninch and associates (1991) found that a renal salvage rate of 89% was possible.

Corriere and colleagues (1991) reported a series of renal units in which vascular control was obtained only if needed after opening the Gerota fascia. In this group, the total nephrectomy rate was 37%. Atala and coworkers (1991) reported a similar group of patients with a total nephrectomy rate of 36%. On the whole, the

currently available data support an improved renal salvage rate with early vascular control because patients who require temporary vascular occlusion cannot be reliably identified before renal inspection. The studies that claim vascular control is unnecessary have an almost threefold higher rate of renal loss than those that always get control.

Renal Reconstruction

The principles of renal reconstruction after trauma include complete renal exposure, measures for temporary vascular control, limited debridement of nonviable tissue, hemostasis by individual suture ligation of bleeding vessels, watertight closure of the collecting system if necessary/possible, reapproximation of the parenchymal defect, coverage with nearby fascioadipose flaps (Gerota fascia or omentum) if feasible, and liberal use of drains (Fig. 50-9).

Renorrhaphy is illustrated in Figure 50-10. Note the approximation of the margins of the laceration (3-0 Vicryl or similar suture) with the use of renal capsule over an absorbable hemostatic agent bolster such as Gelfoam (Pfizer, New York, NY).

When polar injuries cannot be reconstructed, a partial nephrectomy can be performed. The open parenchyma should be covered

when possible by a pedicle flap of omentum (see Fig. 50-9). With its rich vascular and lymphatic supply, omentum promotes wound healing and decreases the risk for delayed bleeding and urinary extravasation. Should it not be available, the use of absorbable mesh, peritoneal graft, or retroperitoneal fat also has been successful.

Hemostatic agents such as Floseal (Baxter, Deerfield, IL) are potent and have an increasing role in the management of genitourinary trauma (Fig. 50-11). Based on experience from nephron-sparing surgery, gelatin matrix was applied to a porcine model of complex renal trauma and demonstrated less mean blood loss than conventional suture treatment (Hick et al, 2005).

In a high percentage of major renal injuries, intra-abdominal structures are also injured, with the liver and spleen being the most common. Injuries to the colon, pancreas, and stomach also occur frequently, and in previous years total nephrectomy was suggested because of the high complication rate with attempted renal salvage. However, renal repair in these injuries has been successful with minimal complications (Rosen and McAninch, 1994; Wessells and McAninch, 1996; Master and McAninch, 2006). Drains should be used liberally after these repairs.

Renovascular Injuries. Renovascular injuries after trauma are uncommon and often have associated injuries requiring operative

Figure 50-10. Technique for renorrhaphy. **A**, Typical injury in midportion of kidney. **B**, Debridement, hemostasis, and collecting system closure. **C**, Approximation of parenchymal margins. **D**, Sutures tied over gelatin sponge bolster.

Figure 50-11. Partial nephrectomy showing excellent hemostasis with use of Floseal only.

intervention. For major renovascular injuries in patients with two kidneys, speedy nephrectomy is advocated. In rare instances in which vascular repair is technically feasible, renal salvage rates are disappointingly low, exemplified by a 33% renal salvage rate for main renal artery reconstruction even in the most expert of hands (Elliott et al, 2007). Vascular repair requires occlusion of the involved vessel with vascular clamps. The lacerated main renal vessels can be repaired with 5-0 nonabsorbable vascular suture (Fig. 50-12).

Main renal artery thrombosis from blunt trauma occurs most often secondary to deceleration injuries. The mobility of the kidney results in stretch on the renal artery, which in turn causes the arterial intima, low in elastic fibers, to disrupt. The consequent thrombus occludes the vessel, rendering the kidney ischemic (Fig. 50-13). Prompt diagnosis by CT or angiography may lead to immediate renal exploration in the appropriate candidate in an attempt to salvage the kidney, but outcomes for salvage remain dismally low, and nephrectomy is almost always required (Knudson et al, 2000).

Case reports of successful renal revascularization through the use of endovascular stents during angiography offer a new and perhaps promising approach to the problem of blunt trauma renal artery thrombosis caused by the intimal flap (Inoue et al, 2004; Memon and Cheung, 2005). The great disadvantage of this approach has

been the inability to safely institute post-stent anticoagulation in the patient with polytrauma.

Surgical revascularization is seldom successful in renal artery thrombosis, and at least 43% of patients with repairs developed hypertension (Haas et al, 1998). Many patients with renal vascular injury are critically injured, with numerous associated organ injuries; time constraints thus limit attempts at vascular repair, and a nephrectomy must be done. Hypertension also was possible in those observed nonoperatively, and subsequent nephrectomy whether immediate, early, or late is almost always required (Knudson et al, 2000).

Injuries to the main renal vein may require repair with fine vascular suture (5-0) (see Fig. 50-12). Partial occlusion of the vein is ideal during repair, but in some instances total temporary occlusion with vascular clamps is necessary.

Damage Control

Coburn (2002) and Pursifull and colleagues (2006) noted the benefit of damage control to improve renal salvage after polytrauma. The area around the injured kidney is packed with laparotomy pads to control bleeding, with a planned return in approximately 24 hours to explore and evaluate the extent of injury. This allows the cold, acidotic, and coagulopathic patient to be stabilized in the ICU before any attempt at potentially lengthy renal reconstruction is attempted. Damage control may allow patients with complex renal injuries to avoid unneeded nephrectomy. This approach is commonly used by trauma surgeons in patients with nonrenal injuries.

Indications for Nephrectomy

The ability to reconstruct an injured kidney depends on numerous factors. In an unstable patient, if damage control is not an option, total nephrectomy would be indicated immediately when the patient's life would be threatened by attempted renal repair. When Nash and colleagues (1995) examined the reasons for nephrectomy in patients with renal injuries, 77% required removal because of the extent of parenchymal, vascular, or combined injury. The remaining 23% required nephrectomy in otherwise reconstructable kidneys because of hemodynamic instability; this should be avoided.

Complications

Persistent urinary extravasation can result in urinoma, perinephric infection, and, rarely, renal loss. These patients are initially

Figure 50-12. Vascular injuries. *Left*, Venous injuries may occur in the main renal vein or the segmental branches. *Middle*, Repair of main renal vein. *Right*, Ligation of segmental branch can be done safely.

Figure 50-13. A, Movement of the kidney from blunt trauma (deceleration injury) causes stretch on the renal artery, resulting in rupture of the arterial intima and formation of a thrombus. B, Computed tomography of a left kidney with renal artery thrombosis, demonstrating lack of contrast material perfusion to the kidney. C, Arteriography demonstrating complete occlusion of the left renal artery (arrow) secondary to thrombus formation.

administered systemic antibiotics, although data supporting their use does not exist. In a high percentage, the extravasation resolves spontaneously (Matthews et al, 1997). Should it persist, placement of an internal ureteral stent often corrects the problem. The addition of a percutaneous nephrostomy or transcutaneously placed urinoma drain may be required in patients not cured by ureteral stent placement.

Delayed renal bleeding can occur up to several weeks after injury but usually occurs within 21 days. The initial management is bed rest and hydration. Should the bleeding persist, angiography frequently can localize the bleeding vessel and embolization often can gain control.

Perinephric abscess rarely occurs after renal injury; persistent urinary extravasation and urinoma are the typical precursors. Urinary drainage with a ureteral stent with or without percutaneous nephrostomy followed by percutaneous abscess drainage offers a good initial method of management, followed by surgical drainage (rarely) if necessary.

Hypertension is seldom noted in the early postinjury period (Monstrey et al, 1989) but can occur later. The basic mechanisms for arterial hypertension as a complication of trauma are (1) renal vascular injury, leading to stenosis or occlusion of the main renal artery or one of its branches (Goldblatt kidney); (2) compression of the renal parenchyma with extravasated blood or urine (Page kidney); and (3) post-trauma arteriovenous fistula. In these instances, the renin-angiotensin axis is stimulated by partial renal ischemia, resulting in hypertension (Goldblatt et al, 1934; Cosgrove et al, 1973).

KEY POINTS: RENAL TRAUMA

- Expectant management strategies of renal trauma allow for maximal renal preservation.
- The degree of hematuria and the severity of renal injury do not consistently correlate.
- Contrast-enhanced CT is the gold standard for genitourinary imaging in renal trauma.
- Patients with microscopic hematuria without shock can be observed clinically without imaging studies.
- Hemodynamically stable, well-staged renal injuries can be conservatively managed (even with high-grade injuries).
- Selective embolization provides an effective and minimally invasive means to stop active bleeding from parenchymal lacerations and segmental arterial injury.
- CT findings suspicious for significant renal injury include (1) medial hematoma (vascular pedicle injury), (2) medial urinary extravasation (renal pelvis or ureteropelvic junction injury), (3) lack of contrast enhancement of the parenchyma (main renal arterial injury), and (4) active intravascular contrast extravasation (arterial injury with brisk bleeding).
- Intraoperative one-shot IVP confirms the presence of a contralateral functioning kidney and may be helpful to define urinary extravasation.
- During renorrhaphy, early vascular control before opening the Gerota fascia can decrease renal loss.

URETERAL INJURIES

Cause

Acute ureteral injury results from external trauma, open surgery, laparoscopy, and endoscopic procedures. Intraoperative suture ligation, sharp incision and transection, avulsion, devascularization, and heat (e.g., microwave, electrocautery, or vibratory energy) or freezing (cryoablation) energies can produce ureteral damage. Additionally, external violence from high-speed blunt mechanisms and penetrating stab and gunshot wounds contributes to the overall incidence. An unrecognized or mismanaged ureteral injury can lead to significant complications, including urinoma, abscess, ureteral stricture, urinary fistula, and potential loss of an ipsilateral renal

TABLE 50-2 American Association for the Surgery of Trauma Organ Injury Severity Scale for the Ureter

GRADE*	TYPE	DESCRIPTION
I	Hematoma	Contusion or hematoma without devascularization
II	Laceration	<50% transection
III	Laceration	≥50% transection
IV	Laceration	Complete transection with <2 cm devascularization
V	Laceration	Avulsion with >2 cm devascularization

unit. Increased nephrectomy rates and a prolonged hospital stay are associated with a delayed or missed diagnosis from penetrating ureteral trauma (Kunkle et al, 2006). Ureteral injuries are often subtle, and clinicians must maintain a high index of suspicion to prevent comorbidity.

External Trauma

Damage to the ureter after external violence is quite rare, occurring in less than 4% of all penetrating and less than 1% of all cases of blunt trauma (Table 50-2). During wartime in the past century, 3% to 15% of urologic injuries have ureteral involvement, with an average of 5% over reports from World War II up to modern conflicts (Busch et al, 1967; Selikowitz, 1977; Marekovic et al, 1997). In the nonmilitary setting, a similar 2% to 3% of ureteral injuries are caused by civilian gunshot wounds. **These patients often have significant concomitant injuries and a devastating degree of mortality that approaches one third** (Medina et al, 1998). Associated visceral injury is common—predominantly small (39% to 65%) and large (28% to 33%) bowel perforation (Presti et al, 1989; Campbell et al, 1992; Medina et al, 1998). A significant percentage (10% to 28%) of patients with ureteral injuries also has associated renal injuries (Presti et al, 1989; Medina et al, 1998). A smaller percentage (5%) has associated bladder injuries (Medina et al, 1998).

The mechanism by which bullets injure the ureter is thought to be similar to the mechanism by which they injure analogous structures such as blood vessels—that is, not only by direct transection but by disruption of the delicate intramural blood supply. In experimental models, such microvascular damage has been found as far away as 2 cm from the point of transection (Amato et al, 1970), although ureters seldom need massive debridement and can generally be minimally debrided back to a bleeding edge. Some authors have even advocated injection of IV fluorescein and examination of the ureter by Wood lamp to ensure viability (Gill and McRoberts, 1992); however, we have not found published evidence to support this technique.

Whereas penetrating trauma imparts a large degree of energy over a small area (as in the course of a bullet), patients with blunt trauma with ureteral injuries are subject to extreme force applied over the entire body, like a fall from heights or a high-speed motor vehicle accident. The great degree of energy imparted to the victim is associated with such uncommon injuries as fractured lumbar processes (Evans and Smith, 1976) and thoracolumbar spinal dislocation (Campbell et al, 1992). The presence of massive force injuries in the patient with blunt trauma should always increase the level of suspicion for ureteral injury.

Patients with penetrating trauma with any degree of hematuria or a wound pattern that suggests the possibility of genitourinary injury should be imaged. Patients with blunt trauma with gross

hematuria or microhematuria plus hypotension, a history of significant deceleration, or significant associated injuries also should be imaged (Mee and McAninch, 1989). Mechanism of injury and physical examination findings must be taken into account. For example, a history of rapid deceleration was found in 100% of patients with ureteropelvic junction (UPJ) injury in one small series (Boone et al, 1993).

Surgical Injury

Any abdominopelvic surgical procedure, whether gynecologic, obstetric, general surgical, or urologic can potentially injure the ureter. The overall incidence of ureteral injury varies between 0.5% and 10% (Al-Awadi et al, 2005). Analysis of 13 published studies concluded that the following procedures contribute to iatrogenic ureteral injuries: hysterectomy (54%), colorectal surgery (14%), pelvic procedures such as ovarian tumor removal (8%), transabdominal urethropyexy (8%), and abdominal vascular surgery (6%) (St. Lezin and Stoller, 1991). One series reported that repeat cesarean section also can result in a large proportion of ureteral injuries, in this case up to 23% of the reported ureteral injuries at one hospital (Ghali et al, 1999). The total incidence of ureteral injury after gynecologic surgery is reported to be 0.5% to 1.5%, and after abdominoperineal colon resection it ranges from 0.3% to 5.7% (St. Lezin and Stoller, 1991). Historically, open urologic procedures, because they often occur in proximity to the ureters, were also responsible for a significant number (21%) of reported ureteral injuries (Selzman and Spirnak, 1996), but they are now extremely rare owing to improved ureteroscopic techniques and equipment.

Vascular Surgery. Intraoperative ureteral manipulation resulting in subsequent hydronephrosis is common after aortoiliac and aortofemoral bypass surgery (12% to 20%), but the course is benign in most (St. Lezin and Stoller, 1991). Surgical devascularization or inflammation can result in symptomatic ureteral stenosis, often delayed in manifestation by months, occurring in only 1% to 2% of these patients (St. Lezin and Stoller, 1991; Adams et al, 1992).

In patients undergoing intra-abdominal vascular surgery, risk factors for surgical injury of the ureter include reoperation; placement of a vascular graft anterior to the ureter (Adams et al, 1992); and large, dilated arterial aneurysms that cause retroperitoneal inflammation that can involve the ureter. The majority (up to 85%) of surgical injuries to the ureter after vascular procedures are not recognized immediately (Adams et al, 1992). Postoperative symptoms of missed ureteral injury include flank pain (36% to 90%), fever, ileus, abdominal distention, and urinary fistula (St. Lezin and Stoller, 1991; Adams et al, 1992).

Ureteroarterial fistulas deserve special mention. This rare and potentially catastrophic condition should be diagnosed and treated immediately because it can cause life-threatening hematuria. The fistula, mostly between the ureter and ipsilateral iliac artery, can be associated with previous pelvic surgery, radiation therapy, long-term indwelling ureteral stents, infection, primary vascular disease, and pregnancy. The experience using endovascular stent grafts for the acute treatment of this devastating event has increased since Kerns and colleagues (1996) first reported success with the technique (Araki et al, 2008). Many will need to be repaired primarily.

Robotic and Laparoscopic Surgery. Since the inception of laparoscopic surgery in the 1960s and robotic surgery in the 1990s, ureteral injuries have occurred (Grainger et al, 1990). The explosion of laparoscopic and robotic surgery into other surgical specialties has meant that the incidence of ureteral injury during and after minimally invasive surgery has likewise skyrocketed. At one center, the incidence of ureteral injuries from laparoscopy went from 0% of all reported ureteral injuries in the early 1980s to 25% of all the reported ureteral injuries only 5 years later (Assimos et al, 1994). As laparoscopic experience grew, that high incidence of injury fell to a baseline of 0.8% on a subsequent review of 1300 laparoscopic urologic procedures (Vallancien et al, 2002). Currently, the reported rate of ureteral injury varies between 0.5% (experienced surgeons) and 14% (inexperienced surgeons) after laparoscopic hysterectomy

(Harkki-Siren et al, 1999; Cosson et al, 2001; Leonard et al, 2007). The rate of urologic injury after robot-assisted surgery is not known yet, but rates of robotic surgery increased more than 1000% over the last decade. Currently, there are early media and legal allegations of increased complications from robotic surgery that are being attributed to the learning curve of the procedure.

A large percentage of ureteral injuries after gynecologic laparoscopy occur during electrosurgical or laser-assisted lysis of endometriosis (Grainger et al, 1990). There are probably three reasons for this: (1) endometrioma can involve the ureter either extrinsically or intrinsically; (2) long-standing endometriosis can cause intraperitoneal adhesion, making ureteral visualization difficult (Ribeiro et al, 1999); and (3) the disease can deviate the ureters medially away from their normal anatomic position (Nackley and Yeko, 2000). A significant number of ureteral injuries also occur during tubal ligation, even when bipolar cautery is used (Grainger et al, 1990).

In 1999 a series of 118 patients reported a 3.4% incidence of ureteral injury after laparoscopic hysterectomy severe enough to cause obstruction (Ribeiro et al, 1999). However, a recent combined series of six larger groups with a much greater number of patients and presumably more experienced surgeons demonstrated a more reasonable 1% rate (Leonard et al, 2007). Of ureteral injuries during hysterectomy, 50% have no identifiable risk factors. The other 50% are associated with malignancy, endometriosis, prior surgery, and surgery for prolapse (Vakili et al, 2005).

Technologic advances have allowed for thermoablative treatment of renal tumors that can result in ureteral damage. There may be a potentially higher risk for ureteral stricturing associated with ablation of medial or lower pole masses. In a porcine model, deliberate targeting of vital renal structures demonstrated an association of ureteropelvic fistula and injury with radiofrequency ablation (Brashears et al, 2005). With experience, the real clinical risks have decreased. A recent multi-institutional review of 271 thermoablative procedures for small renal tumors reported only one ureteral injury (Johnson et al, 2004).

In contradistinction to open operation, in which at least one third of ureteral injuries are recognized immediately (Rodriguez and Payne, 2001), fewer injuries to the ureter are immediately identified after laparoscopy (Grainger et al, 1990; Parpala-Sparman et al, 2008). Therefore, during laparoscopy and robotic surgery, a high index of suspicion for ureteral injury is required. The symptoms may develop acutely or insidiously, depending on the mechanism. Postoperatively, patients must be monitored for fever, peritonitis, and leukocytosis (Grainger et al, 1990; Parpala-Sparman et al, 2008), which herald the potential for missed ureteral injury. A smaller number of patients with missed ureteral injury present with hematuria or a pelvic mass representing urinoma (Grainger et al, 1990). A low threshold for postoperative imaging is required, especially in those with these symptoms.

Avoiding and Detecting Ureteral Injury. Avoidance of ureteral injury is predicated on intimate knowledge of its location, especially its relation to the uterine and ovarian arteries, if those structures are going to be ligated, as in a hysterectomy (Fig. 50-14). Visualization of the ureter in the area of the uterosacral ligaments is thought to be especially difficult, and special care must be taken in this area (Grainger et al, 1990). It is axiomatic that ureteral injury is more likely in cases of uncontrolled bleeding, and adequate intraoperative hemostasis and surgical exposure should further decrease these injuries, even in high-risk cases (Cosson et al, 2001; Liapis et al, 2001). Intraoperative hydration or diuretic administration has been suggested to enhance ureteral visualization and potentially decrease the risk for injury, although data to support this claim do not exist. Preoperative ureteral stenting can be used to ease identification of the ureter in high-risk cases; however, published data in the gynecologic and colectomy population show that, although it may increase intraoperative recognition of ureteral injury, it may not actually decrease ureteral injuries (Leff et al, 1982; Bothwell et al, 1994; Kuno et al, 1998). Ureteral stents are not without complications; the rate of anuria after bilateral prophylactic ureteral stent placement has been reported between 1% and 5%

Figure 50-14. Ureteral anatomy showing relationship to fallopian tube and uterine artery.

(Leff et al, 1982; Sheikh and Khubchandani, 1990; Kyzer and Gordon, 1994), and the rate of iatrogenic ureteral injury during stent placement 1% (Bothwell et al, 1994). One study showed that stents might even increase rather than reduce the chance for intraoperative injury (Dowling et al, 1986). Ureteral stent placement is not always successful; stents cannot be placed on one side in 13% of cases, and total failure to place either catheter can occur in 2% (Bothwell et al, 1994). Lighted fiberoptic ureteral catheters have been used with good effect (Ben-Hur and Phipps, 2000), and newer, smaller 5-Fr models may avoid the complications of ureteral edema and obstruction, which have been reported after the use of larger, older-model lighted stents (Chahin et al, 2002).

Some authors have advocated maneuvers to check the patency of the ureter after all surgeries in which ureter injury is commonly reported (e.g., hysterectomy). Cystoscopy without indigo carmine/methylene blue administration, used to document the absence of hematuria and the presence of bilateral ureteral jets, is a poor predictor of injury. In one decade-long study, it missed more injuries than it detected (Dandolu et al, 2003). In another, it increased the detection rate from 30% to 96% (Vakili et al 2005), showing a benefit. Purposefully opening the retroperitoneum before or after hysterectomy has been advocated to avoid ureteral injury or at least allow intraoperative detection. A majority of authors on the subject advocate this approach (Cruikshank, 1986; Neuman et al, 1991; Cosson et al, 2001; Liapis et al, 2001); one author suggests it may contribute to ureteral devascularization by inadvertent disruption of the delicate distal ureteral blood supply (Nezhat et al, 1995). Mere digital palpation of the ureter, perhaps through the unopened retroperitoneum, appears to be ineffective (Symmonds, 1976). Some nonurologists have advocated grasping the ureter with forceps to evoke ureteral peristalsis as a measure of an uninjured ureter, but this is highly ineffective and should never be relied upon. Finally, some authors recommend injection of 5 to 10 mL of IV indigo carmine dye followed by cystoscopy to ensure patency of the ureters after laparoscopic hysterectomy. When this technique was used in

118 patients undergoing laparoscopic hysterectomy, 4 of 4 cases of ureteral occlusion were identified immediately (mostly caused by suture ligation) and repaired immediately without complications (Ribeiro et al, 1999).

Note that IV methylene blue and indigo carmine are generally considered by most urologists to be benign drugs, but their use has resulted in patient deaths and fetal deaths when used in pregnant women. It always must be avoided in pregnant women and in patients who are taking selective (e.g., paroxetine, sertraline, fluoxetine, fluvoxamine, citalopram) or nonselective (e.g., imipramine) serotonin reuptake inhibitors. Methylene blue is a potent monoamine oxidase inhibitor and has caused deaths from serotonin toxicity in patients taking medications that increase serotonin levels. IV methylene blue also should be avoided in patients with glucose-6-phosphate dehydrogenase deficiency because it can cause methemoglobinemia and hemolysis. IV indigo carmine is implicated in rare but serious cases of bronchospasm, bradycardia, hypotension, hypotension (most common), and anaphylactoid reactions (Jeon et al, 2012).

The Tenuous Ureteral Blood Supply. The distal ureteral blood supply is variable (Daniel and Shackman, 1952). It is estimated by cadaver studies that 10% of females carry a disproportionate amount of their distal ureteral blood supply via uterine artery branches. These branches are necessarily severed when the uterine artery is ligated during the course of a normal hysterectomy. It has been experimentally proved on cadavers that 40% of females have decreased ureteral perfusion after ligating the uterine artery. The resultant hypothesis is that distal ureteral devascularization may be an unavoidable consequence in a small percentage of women after hysterectomy (Michaels, 1948). Ureteral devascularization tends to manifest differently from other ureteral injuries. Patients tend to present late (more than a week after surgery, but as late as 1 to 2 months), usually with ureteral stenosis, urinoma, or even uretero-vaginal fistula that was not seemingly present at the time of surgery or the early days after surgery.

Ureteroscopic Injury

Since Kaufman (1984) first reported ureteral injury after rigid ureteroscopy in 1984, countless ureteral misadventures have resulted from this procedure. In fact, ureteroscopic injury was the most common cause of iatrogenic ureteral trauma in some modern series (Johnson et al, 2004). In the late 1980s, an explosion of ureteral injuries coincided with the widespread use of ureteroscopy (Huffman, 1989). Improvements in equipment and operator experience subsequently decreased the rate of ureteral perforation, to a stable average of 7% in the 1990s (range 0% to 28%) (Huffman, 1989). More recent expert series have a perforation rate of 1% to 5% (Schuster et al, 2001), of which 0.2% requires open surgery (Butler et al, 2004) with an additional 5% incidence of delayed stricture occurrence (Schuster et al, 2001).

One factor cited as a cause of ureteral injury during ureteroscopy was the persistence of stone basket attempts after recognition of a ureteral tear. Current recommendations are to stop the procedure and place a ureteral stent when ureteral perforations are identified (Chang and Marshall, 1987). The wide use of the holmium:yttrium-aluminum-garnet (Ho:YAG) laser to fragment larger stones before basket manipulation is attempted should further decrease the potential for this complication (Bagley et al, 2004). Extraureteric extrusion of calculi during laser fragmentation or basket retrieval has shown to be a minor complication and only rarely leads to stricture formation (Kriegmair and Schmeller, 1995).

It is also recommended to perform ureteroscopy alongside or over a wire placed up into the renal pelvis (Chang and Marshall, 1987; Flam et al, 1988), although some experts no longer use a safety wire during routine flexible ureteroscopy (Bratslavsky and Moran, 2004). This wire facilitates not only safe ureteroscopy but also placement of a ureteral stent later in the case if necessary. Factors associated with higher complication rates during ureteroscopy were longer surgery times, treatment of renal calculi, surgeon inexperience, and previous irradiation (Huffman, 1989;

Schuster et al, 2001; Fuganti et al, 2008). During stone fragmentation attempts, electrohydraulic lithotripsy (now hardly used) is associated with the highest risk for ureteral injury, followed by the neodymium:YAG (Nd:YAG) laser and finally by the Ho:YAG laser (Johnson and Pearle, 2004). Factors that are thought to protect against ureteral injury are smaller (Flam et al, 1988; Huffman, 1989) and flexible ureteroscopes (Huffman, 1989). Ureteral access sheaths also protect the ureter, but the sheaths themselves can cause ureteral wall injury, especially if the patient did not receive a ureteral stent preoperatively (Traxer and Thomas, 2013). Smaller diameter (≤ 14 -Fr) sheaths are preferred for nonstented ureters.

Diagnosis

Gunshot and Stab Wounds

Hematuria. Hematuria is a nonspecific indicator of urologic injury. Significant ureteral injury can occur in the absence of hematuria (Elliott and McAninch, 2006). Because many (25% to 45%) cases of ureteral injury after violence do not demonstrate even microscopic hematuria (Presti et al, 1989; Campbell et al, 1992; Brandes et al, 1994; Palmer et al, 1999), a high index of suspicion is required in cases of potential ureteral injury after penetrating trauma.

Intraoperative Recognition. In an analysis of previously published reports concerning ureteral injury from external violence, Armenakas and associates (1999) noted that 93% of injuries were recognized promptly, including 57% that were identified intraoperatively. We and others (Brandes et al, 1994; Medina et al, 1998) make every attempt to diagnose these injuries during exploration. Intraoperative detection requires a high degree of suspicion, but there is evidence that specific vigilance for ureteral injuries may decrease the incidence of missed injuries (McGinty and Mendez, 1977). The trajectory of the knife or missile must be carefully examined during laparotomy and ureteral exploration undertaken in all cases of potential injury. With a 75% sensitivity for traumatic ureteral injury, wound location may be the only indicator for identifying ureteral injury in the acute setting (Elliott and McAninch, 2003). Liberal use of preoperative diagnostic tools (urinalysis, IVP, CT), even if imperfect, is helpful. Intraoperative recognition of ureteral or renal pelvis injury may be aided by using a small needle to inject 1 to 2 mL of methylene blue (10 mg/mL) directly into the renal pelvis. Care must be taken not to inject excessive dye, because it can spill and stain local tissues, making dye determination of the source of leak impossible.

Inadequate exploration or a low index of suspicion in the presence of multiple injuries is often responsible for missed ureteral injury. In the largest meta-analysis to date, analyzing 16 busy trauma centers with 429 ureteral injuries with laparotomy, a collective 11% miss rate of ureteral injury was noted (Kunkle et al, 2006). Delayed diagnosis in that series was associated with a prolonged hospital stay and increased rates of nephrectomy. An unrecognized or undertreated ureteral injury can lead to other significant complications, including urinoma, abscess, ureteral stricture, and urinary fistula.

Vigilance for delayed presentation of ureteral injuries allows detection of initially missed injuries. Fever, leukocytosis, and local peritoneal irritation are the most common signs and symptoms of missed ureteral injury and always should prompt CT examination. In contrast to acute injuries, “missed” injuries that are discovered more than 48 hours after injury may be best diagnosed with retrograde ureterography if possible. This procedure has the added benefit of allowing immediate attempts at ureteral stent passage to aid urinary drainage, avoid or treat urinoma, and allow healing without further surgery in rare cases.

Imaging Studies

Excretory Urography. Ureteral injuries after external violence, unlike renal injuries, are difficult to detect with the usual array of diagnostic tools: preoperative urinalysis, CT scan, and intraoperative one-shot IVP. IVP is often unhelpful, proving nondiagnostic 33% to 100% of the time (Palmer et al, 1983; Presti et al, 1989; Campbell et al, 1992; Brandes et al, 1994; Azimuddin et al, 1998; Elliott and McAninch, 2003). However, in the absence of a better

Figure 50-15. Excretory urography demonstrating extravasation in the upper right ureter consequent to stab wound. Note lack of contrast (arrow) in the ureter below the site of injury, indicating complete ureteral transection.

test, we still recommend intraoperative one-shot pyelography together with intraoperative inspection to detect ureteral injuries and assess the functional status of the contralateral system. When intraoperative one-shot IVP abnormalities are found, obvious contrast extravasation can sometimes be seen (Fig. 50-15). However, IVP findings are often subtle and nonspecific (e.g., delayed function, ureteral dilation, and ureteral deviation). Insensitivity of these usual diagnostic tools and high false-negative rates are some of the reasons why delay of detection occurs in 8% to 20% of cases (Presti et al, 1989; Brandes et al, 1994; Palmer et al, 1999).

Computed Tomography. CT is used increasingly in the evaluation of the trauma patient, and although it appears promising in detecting ureteral injuries (Kawashima et al, 2001), there are only a handful of published reports (Kenney et al, 1987; Townsend and DeFalco, 1995). Ureteral injuries can be difficult to diagnose on CT. If the urinary extravasation from upper ureteral injury is contained by the Gerota fascia, the extent of medial leakage can be small, obscuring the diagnosis (Kenney et al, 1987). It is also known that ureteral injuries often manifest with absence of contrast in the ureter on delayed images. This underscores the absolute necessity of tracing both ureters throughout their entire course on CT scans obtained to evaluate urogenital injuries (Townsend and DeFalco, 1995). Because modern helical CT scanners can obtain images rapidly, before IV contrast dye is excreted in the urine, delayed images must be obtained (5 to 20 minutes after contrast injection) to allow contrast material to extravasate from the injured collecting system, renal pelvis, or ureter (Brown et al, 1998b; Mulligan et al, 1998; Kawashima et al, 2001). Because ureteral injuries are often detected late, periureteral urinoma seen on delayed CT scans may be diagnostic (Gayer et al, 2002).

In reported series, all patients with significant ureteropelvic laceration, for instance, had either medial extravasation of contrast material or nonopacification of the ipsilateral ureter on CT (Kenney

Figure 50-16. Computed tomography showing right medial extravasation of contrast material in a patient with a renal pelvis laceration.

et al, 1987; Kawashima et al, 2001) (Fig. 50-16) or a “circumrenal” contrast extravasation (Kawashima et al, 1997).

Retrograde Ureterography. Retrograde ureterograms, the most sensitive radiographic test for ureteral injury, are used in some centers as a primary diagnostic technique to detect acute ureteral injuries (Campbell et al, 1992); however, we tend to use noninvasive methods such as one-shot IVP and CT scan to make the diagnosis intraoperatively when feasible. Retrograde ureterography is used, however, to delineate the extent of ureteral injury seen on CT scan or IVP if further clinical information is needed. Retrograde ureterography is most commonly used to diagnose initially missed ureteral injuries, because it allows the simultaneous placement of a ureteral stent if possible.

Antegrade Ureterography. Antegrade ureterography is seldom used in our practice. In cases in which ureteral injury is discovered, we most often plan retrograde ureterography and stent placement or open repair. If retrograde stent placement is not possible (usually secondary to a large gap in the two ends of the transected ureter), we attempt antegrade ureterography and stent placement at the time of percutaneous nephrostomy placement (Toporoff et al, 1992).

Management

See Figure 50-17.

General Principles

Following certain general principles of ureteral surgery increases the success rate of this delicate surgery. Repair of the ureter must be meticulous (Fig. 50-18). Ureteral blood supply is tenuous, and a sequela of imperfect repair can be urine leakage that can result in patient debility, nephrectomy, and, in rare cases, even death. Principles of management of the injured ureter are as follows:

1. Mobilize the injured ureter carefully, sparing the adventitia widely, so as not to devascularize the ureter further.
2. Debride the ureter minimally but judiciously until edges bleed, especially in high-velocity gunshot wounds.
3. Repair ureters with spatulated, tension-free, stented (Palmer et al, 1983), watertight anastomosis, using fine absorbable monofilament such as 5-0 polydioxanone and retroperitoneal drainage afterward. Use optical magnification if necessary.
4. Retroperitonealize the ureteral repair by closing peritoneum over it if possible.
5. Do not tunnel ureteroneocystostomies but rather create a widely spatulated nontunneled anastomosis.

Figure 50-17. Suggested management options for ureteral injuries at different levels.

6. With severely injured ureters, blast effect, concomitant vascular surgery, and other complex cases, consider omental interposition to isolate the repair when possible.
7. If immediate repair is not possible, tie off the ureter with long silk sutures and plan to repair it later (damage control). Ipsilateral drainage can be achieved by placing a single J stent brought out cutaneously or a percutaneous nephrostomy tube placed later.

External Trauma

Contusion. Ureteral contusions, although the most minor of ureteral injuries, can heal with stricture or breakdown later if microvascular injury results in ureteral necrosis, with an incidence that is not currently known. **Severe or large areas of contusion should be treated with excision of the damaged area and ureteroureterostomy/ureteroneocystostomy.** The safest approach in ureteral contusions that do not appear to require excision/anastomosis is to place a ureteral stent. Only truly minor injuries can go untreated, but the patients should be watched for signs of delayed urine leak.

Management of ureteral leak is by percutaneous nephrostomy placement and ureteral catheter placement for at least 6 weeks, which provides surprisingly good success rates (83% [Toporoff et al, 1992] to 88% [Lang, 1984]). Other authors have recommended stenting for a longer period—up to 8 weeks (Steers et al, 1985).

Upper Ureteral Injuries

Ureteroureterostomy. Ureteral avulsion from the renal pelvis, or even very proximal ureteral injury, can be managed by reimplantation of the ureter directly into the renal pelvis (Fig. 50-19). These can be done open, laparoscopically, or robotically (Mufarrij et al, 2007). Ureteroureterostomy, or so-called end-to-end repair, is used in injuries to the upper two thirds of the ureter. It is required commonly—up to 32% of the time in large series (Presti et al, 1989; Elliott and McAninch, 2003)—and has a reported success rate as high as 90% (Carlton et al, 1971). Complications after ureteroureterostomy, usually urine leakage, occur 10% to 24% of the time (Bright and Peters, 1977a; Pitts and Peterson, 1981; Presti et al, 1989; Campbell et al, 1992; Velmahos et al, 1996; Medina et al, 1998). Other acute complications include abscess and fistula. Chronic complications, usually ureteral stenosis, are less common, involving approximately 5% (Palmer et al, 1999) to 12%

Figure 50-18. Technique of ureteroureterostomy after traumatic disruption. A, Injury site definition by ureteral mobilization. B, Debridement of margins and spatulation. C, Stent placement. D, Approximation with 5-0 absorbable suture. E, Final result.

Figure 50-19. Proximal ureter is spatulated and sutured to the renal pelvis.

(Velmahos et al, 1996) of patients. Interestingly, some authors report prolonged leakage of urine from the drain in patients with ureteral injury after external violence who underwent repair but otherwise did well. Steers and colleagues (1985) reported that most of their patients had persistent drainage (averaging 12 days) from the retroperitoneal Penrose drain after repair. This has not been our experience, but this observation might prompt watchful waiting in such patients who leak persistently after repair. Routine retroperitonealization of the repair may decrease the time or severity of postoperative urine leakage.

Rarely, ureterocalycostomy, in which the ureteral stump is sewn end-to-side into an exposed renal calyx, also can be used where there is profound damage to the renal pelvis and UPJ (Matlaga et al, 2005). This is a technically challenging case. It can be difficult to find an inferior calyx; it requires renal surgery equivalent to a partial nephrectomy; and sewing the small, medially located ureter to a large laterally located renal calyx can be difficult or even impossible. With technologic advances, robotics can be successfully and safely used for a wide variety of delayed upper urinary tract reconstructions, including dismembered pyeloplasty, ureteroureterostomy, and ureterocalycostomy.

Autotransplantation. Autotransplantation of the kidney has been used after profound ureteral loss or after multiple attempts at ureteral repair have failed. This maneuver remains the final option before nephrectomy. Despite great efforts, renal units are sometimes lost after autotransplantation, occurring in 4 of 39 kidneys in two

Figure 50-20. Nontapered distal ileal segment is anastomosed to the bladder in a wide open fashion.

combined series (Bodie et al, 1986; Eisenberg et al, 2008), although centers with significant transplant experience have reported good results.

Bowel Interposition. Delayed ureteral repairs, especially when a very long segment of ureter is destroyed, also can be performed by creation of a ureteral conduit out of ileum in much the same way that an ileal conduit is constructed to drain the urine after cystectomy. Success rates for ileal replacement of the ureter have been reported to be 81% (Boxer et al, 1979; Verduyck et al, 2002) to 100% (Matlaga et al, 2003; Bonfig et al, 2004). A recent review of long-term complications of 99 renal units reported a 3% anastomotic stricture and 6% fistula rate (Armatys et al, 2009). Some have used the Monti procedure, in which short segments of small or large bowel are formed into a long, thin tube successfully in ureteral reconstruction (Ubrig et al, 2001; Ali-el-Dein and Ghoneim, 2003). Laparoscopic-assisted ureteral interposition by ileum has been described in two patients (Castillo et al, 2008). The use of appendix in open (Jang et al, 2002) and laparoscopic (Reggio et al, 2008) ureteral substitution has also been reported. Although most practitioners create a wide-open, refluxing, ileal replacement of the ureter (Fig. 50-20), it appears that significant clinical reflux is not a problem (Waldner et al, 1999). We often prefer a standard ileal ureter technique instead of tapered bowel or appendix because patients place a premium on the reliability of the repair, and in our experience the ileal ureter operation is very reliable. Ileal interposition is not suggested for acute repair of ureteral injury but rather would be used in delayed or staged repairs.

Monitoring after Ureteral Repair. Monitoring after ureteral repair is a matter of personal preference. We tend to leave the stent in for 6 weeks. At the time of stent removal, we usually perform a retrograde ureterogram to document healing without leakage or stenosis. One month postoperatively, we perform a furosemide (Lasix) renogram to document that the system continues to be unobstructed. Four months postoperatively we perform a renal ultrasound to document lack of hydronephrosis, which itself might indicate late obstruction. Ureteral injury repairs often happen in the setting of ureteral devascularization; late stenosis can occur.

Nephrectomy. Rarely, acute nephrectomy is required to treat ureteral injury after external violence. Reasons for nephrectomy include associated severe visceral injuries (although damage control without nephrectomy is nearly always preferable) or severe associated injury to the ipsilateral kidney when renal repair is not possible (McGinty and Mendez, 1977; Gill and McRoberts, 1992). Delayed nephrectomy may be required because of poor renal function (which can sometimes be seen after delayed recognition of an obstructing ureteral injury), severe panureteral injury when ileal ureter or other reconstruction is impossible, or persistent ureteral fistula (especially vascular fistula) despite previous intervention (Ghali et al, 1999). In general, nephrectomy must be avoided if at all possible.

Midureteral Injuries

Transureteroureterostomy. A rarely used (Presti et al, 1989) but often (90% to 97%) successful (Rainwater et al, 1991; Sugarbaker et al, 2003) technique in adults is transureteroureterostomy. Pediatric series show a lower success rate of 70% (Mure et al, 2000). This form of repair involves bringing the injured ureter across the midline and anastomosing it end-to-side into the uninjured ureter and is most often performed as a secondary or delayed procedure. It also might be mandated in some cases of middle or distal ureteral injury in which ureteroureterostomy or bladder flap/hitch repair is impossible (usually because of severe bladder scarring, a congenitally small bladder, or a very long segment of missing ureter). Laparoscopic transureteroureterostomy has been performed in the pediatric population (Piaggio and González, 2007).

However, transureteroureterostomy leaves the patient and urologist with some vexing problems postoperatively. The injured ureter becomes difficult to intubate or image with ureteroscopy through the bladder; ureteral access needs to be provided by a nephrostomy placed on the injured side. Some authors feel this operation is contraindicated in patients with a history of urothelial cancer or calculi, although this information is seldom available to the operating trauma surgeon. Caution is required while performing this procedure because it involves surgery on the uninjured, contralateral ureter with the theoretical risk for converting unilateral ureteral injury into (iatrogenic) bilateral ureteral injury. Instead of transureteroureterostomy, we prefer either ileal interposition or ureteroureterostomy with renal mobilization if necessary.

Lower Ureteral Injuries

Ureteroneocystostomy. Ureteroneocystostomy is used to repair distal ureteral injuries that occur so close to the bladder that the bladder does not need to be brought up to the ureteral stump with a psoas hitch or Boari procedure. Standard principles of ureteroneocystostomy include a long, nontunneled, spatulated, stented anastomosis. Refluxing ureteroneobladder (Minervini et al, 2005) and uretero-ileal loop (Wiesner and Thuroff, 2004) anastomoses show no increase in complications related to urine reflux, although these populations of patients are different from the average trauma population and reports do not address whether ureteral implantation into the native bladder is equally safe. Further study is needed to resolve this issue, but we favor nontunneled anastomoses because we prefer the low risk for clinically significant reflux to the higher risk for ureteral obstruction using a tunneled approach.

Psoas Bladder Hitch. The psoas hitch procedure (Fig. 50-21) is a mainstay in the treatment of injuries to the lower third of the ureter and has a high success rate, from 95% to 100% (Middleton, 1980; Riedmiller et al, 1984; Ahn and Loughlin, 2001). We prefer it over ureteroureterostomy in lower ureteral injuries because the tenuous ureteral blood supply might not survive transection. Some authors prefer end-to-end repair in lower ureteral injuries when the distal stump is preserved (Paick et al, 2006).

Boari Flap. Injuries to the lower two thirds of the ureter with long ureteral defects (too long to be bridged by bringing the bladder up in the psoas hitch procedure) can be managed with a Boari flap or a transureteroureterostomy (Fig. 50-22). In this case, a pedicle of bladder is swung cephalad and tubularized to bridge the gap to the injured ureter. The procedure is time-consuming, however, and is not appropriate for most acute injuries. It is not commonly performed, but authors report a high success rate (Benson et al, 1990).

Minimally Invasive. More recently, laparoscopic and robotic repair of distal ureteral injuries has emerged as a viable alternative to open surgery (Mufarrij et al, 2007). Laparoscopic direct ureteroneocystostomy, psoas bladder hitch, and Boari flap reconstructions have been described (Fugita et al, 2001; Schimpf and Wagner, 2008). A review of early results demonstrates laparoscopic ureteral reimplantation as effective as open techniques (Ogan et al, 2008). In a recent study of 45 patients undergoing laparoscopic ureteroneocystostomy, overall success, defined as radiographic evidence of no residual obstruction, symptoms, renal deterioration, or need for subsequent procedures was 96% (Seideman et al, 2009). Although limited data exist and longer term outcomes are needed, many centers now use

Figure 50-21. Psoas hitch. Bladder is opened and secured to the psoas muscle to facilitate ureteral anastomosis. (From Hohenfellner M, Santucci RA. *Emergencies in urology*. Heidelberg (Germany): Springer; 2007. © Copyright, 2007 Dr. Markus Hohenfellner, with permission.)

laparoscopic and even robotic management as primary treatment. Laparoscopic or robotic repair of ureteral injuries may indeed be the standard of care.

Partial Transection. Primary repair of a partial transection is used in the majority of ureteral injuries, up to 58% of the time in one large series (Presti et al, 1989). Principles of primary repair involve spatulated, watertight closure, with interrupted or running 5-0 or 6-0 absorbable monofilament such as Maxon (polyglyconate) or Dexon (polyglycolic acid). The ureteral injury is closed by converting a longitudinal laceration into a transverse one so as not to narrow the ureteral lumen (Heineke-Mikulicz procedure) and repeat retroperitonealized if possible. An internal stent and retroperitoneal drain are always placed.

Damage Control. In cases of ureteral injury after external violence, it is sometimes necessary to treat the injured ureter by deferring definitive treatment until later. This is usually because the patient is too unstable to tolerate the operative time required to complete the repair (Cass, 1983). Some have suggested that in cases of severe hemorrhagic shock, uncontrollable intraoperative bleeding, or severe colon injury (especially those requiring colectomy), ureteral repair should be avoided in favor of nephrectomy or staged repair (Velmahos et al, 1996).

The four options for damage control in ureteral injuries are (1) do nothing, but plan a reoperation when the patient is more stable, usually within 24 hours; (2) place an internal or exteriorized ureteral stent and do nothing else; (3) exteriorize the ureter; or (4) tie off the ureter and plan percutaneous nephrostomy (Hirshberg et al, 1994). In most cases of planned staged repair, we tie off the damaged ureter, using long silk ties to aid the dissection of the ureteral stump during the second-stage repair. The kidney is then drained percutaneously. We advocate percutaneous (not intraoperative or intra-abdominal) placement of a nephrostomy tube, either by the surgeon just postoperatively or later by interventional radiologists. We have

found that intraoperative open nephrostomy placement can be too time-consuming in these unstable patients. Alternatively, a single J stent can be placed into the ureter, the distal ureteral injury tied off over the stent, and the stent end externalized through the abdominal wall (Gill and McRoberts, 1992; Ball et al, 2005). If possible, appropriate planned ureteric reconstruction should be done after functional and anatomic imaging is performed.

Surgical Injury

Timing of Repair. The ideal timing of curative surgery is controversial. Experts suggest fixing intraoperatively discovered injuries immediately. Even with immediate recognition, success is not ensured. In small series, patients with immediately repaired ureteral injuries still suffered urine leak, fistula, and even nephrectomy (Grainger et al, 1990; Mandal et al, 1990). Experts suggest that postoperatively discovered injuries be immediately repaired when detected within 72 hours. Injuries discovered after this 3-day period are drained with stent, percutaneous nephrostomy, or both, and definitive repair is delayed until 6 weeks after injury. This putatively avoids an inflammatory phase, when ureteral repairs are thought to be less reliable. Others recommend immediate repair whenever injuries are discovered, even in the 3- to 42-day window that some avoid surgery. These authors cite low complication rates, similar to injuries that are recognized immediately (Witters et al, 1986; Ghali et al, 1999). However, delayed diagnosis of ureteral injury may increase the complication rate of the repair significantly (Selzman and Spirnak, 1996), from 10% to 40% in one series (Campbell et al, 1992). Some have suggested that delaying the repair (6 weeks) avoids this risk (Cangiano and deKernion, 1988).

In the period between 3 and 42 days after injury, discovering the injury “early” (say, in the first week) versus late (say, after a month) does not seem to affect outcomes. Most injuries, in fact, are

Figure 50-22. Boari flap. Bladder flap is marked (A), mobilized free (B), tubularized (C). (From Hohenfellner M, Santucci RA. *Emergencies in urology*. Heidelberg (Germany): Springer; 2007. © Copyright, 2007 Dr. Markus Hohenfellner, with permission.)

Figure 50-23. A, Left nephrostogram showing abrupt mid-ureteral cutoff consistent with (inadvertent) suture ligation of the ureter. B, Intraoperative view of left mid-ureteral suture ligation.

discovered in this period (Oh et al, 2000; Hatch et al, 1984), and in one series almost half were discovered more than 6 weeks after the initial surgery (Badenoch et al, 1987). Cure rates appear equal in the early and late discovery groups (Brandt et al, 2001; Liapis et al, 2001).

Ligation. Ligation of the ureter should be treated by removal of the ligature and observation of the ureter for viability. If viability is in question, ureteroureterostomy or ureteral reimplantation should be performed (Assimos et al, 1994; Brandes et al, 2004) (Fig. 50-23). Placement of a ureteral stent, by opening the bladder or by immediate cystoscopic placement, is highly advised.

Transection

Immediate Recognition. Injuries discovered immediately after nonaortic surgery are largely treated in the same way as ureteral injury after external violence. Most lacerations can be treated with ureteroureterostomy, although additional maneuvers such as omental wrapping of the repair or placement of an ipsilateral nephrostomy tube have been advocated to decrease the potential for urine leakage or breakdown of the repair (Adams et al, 1992). With increasing laparoscopic and robotic popularity, many of these injuries are now being treated without the need for open conversion (Dinlenc et al, 2004; Ou et al, 2005). Ureteroscopic (Tsai et al, 2000) ureteroureterostomies for operative ureteral injuries also have been reported, although we have no direct experience with them.

Ureteral injuries that occur during vascular graft surgery are a special case. Intraoperative management of these should be primary ureteroureterostomy with isolation of the repair with omentum (Adams et al, 1992). Nephrectomy in cases of ureteral injury should be avoided. Although nephrectomy avoids the potential for postoperative urine leakage around an aortic or iliac vascular graft (Schapira et al, 1981), it increased the mortality rate. In patients with a ruptured aneurysm, it can increase the fatality rate fourfold, from 3% to 12% (Schapira et al, 1981). We recommend careful repair of the ureteral injury, reserving nephrectomy for patients who develop urine leakage postoperatively.

Delayed Recognition. Intraoperative recognition of ureteral injuries occurs in as few as 34% of patients undergoing open operation

(Ghali et al, 1999) and as few as 0% of those undergoing laparoscopy (Grainger et al, 1990). Delayed diagnosis of ureteral injury is most often (66% [Ghali et al, 1999] to 76% [Grainger et al, 1990]) achieved by CT pyelography, IVP, or retrograde ureterography (Grainger et al, 1990). In a series of 35 ureteral injuries, patients present with a variety of signs and symptoms: anuria (14%, most with bilateral injury), urogenital fistula (11%), persistent pain or fever (9%), urinary leakage from the wound (9%), hydronephrosis (3%), and hematuria (3%) (Ghali et al, 1999). Some authors cite a triad of fever, leukocytosis, and generalized peritoneal signs as being most diagnostic for missed ureteral injury (Medina et al, 1998). Repair of these delayed-recognition injuries is controversial. Some advocate immediate attempt at placement of a double-J ureteral stent (Bright and Peters, 1977b), but this is not always possible. Reported success varies widely: 5% to 10% (Dowling et al, 1986; Hoch et al, 1975), 20% (Ghali et al, 1999; Oh et al, 2000), and 50% (Cormio et al, 1993). When stent placement is possible, some authors have reported a spontaneous healing rate as high as 73% (Dowling et al, 1986) or as low as 0% (Oh et al, 2000). Usually, failure to place a stent is due to complete obstruction of the ureter or to too long a gap (Cormio et al, 1993). Some authors have suggested that stenting alone has the highest failure rate in those with multiple previous pelvic operations, radiation therapy, or significant previous ureteral surgery (Chang and Marshall, 1987). The ideal length of time to leave the stent has never been studied in a randomized, prospective, double-blind fashion, but some authors recommend at least 6 weeks (Selzman and Spirnak, 1996). Some authors had increased healing rates when stents are left in for 3 months (Cormio et al, 1993), although this has not been observed in our practice. Most authors report low rates of spontaneous healing with stenting alone; in a series of ureteral injuries after laparoscopies that were recognized late (3 to 33 days after surgery), all ultimately required open repair (Oh et al, 2000). The literature and our experience seem to indicate that a majority of patients will require definitive repair of significant ureteral injuries, whether stent placement is possible or not. If stents cannot be placed, the urine must still be drained and percutaneous nephrostomy should be placed.

We first attempt retrograde placement of a ureteral stent in most cases of delayed recognition of ureteral injury. If stent placement is achieved, open repair is planned only in patients with persistent leakage or significant ureteral stricture (Dowling et al, 1986; Cormio et al, 1993). In cases in which we cannot place a retrograde ureteral stent, we usually place a nephrostomy tube and make an immediate or delayed attempt at antegrade stenting of the injury. If this initially fails, we place a nephrostomy tube and wait 7 to 14 days to reattempt antegrade ureteral stenting. We and our patients highly prefer internalized double-J stents over percutaneous nephrostomies whenever possible. Ureteral balloon catheters, which are designed to stop urine from traveling down the ureter, have been advocated if simple stenting does not eliminate associated urine leakage or urinoma, although we often have found them to be ineffective. If the ureter ultimately cannot be stented, a percutaneous nephrostomy is placed. We think the safest approach is to allow at least 6 weeks for complete healing of the wounds, then attempt open repair. Some have reported the requirement for even longer ureteral drainage in certain special cases, such as in the presence of ureteroenteric fistula (Bright and Peters, 1977b). We recognize that some experts in the field repair these injuries whenever they are discovered, with seemingly good results (Bright and Peters, 1977b; Flynn et al, 1979; Blandy et al, 1991; Oh et al, 2000).

Some authors have advocated treating postinjury ureteral stenosis endoscopically with either balloon dilation (Richter et al, 2000) or laser incision (Singal et al, 1997; Patel and Newman, 2004). Others have used endoluminal stents for ureteral obstruction after injury with good results in limited numbers of patients (Yohannes et al, 2001; Wenzler et al, 2008). We personally have had poor results after endoscopic dilation and incision techniques in the long, devascularized, postinjury or postoperative ureteral strictures that seem to dominate our practice, although we may try them in short, uncomplicated strictures before open repair is contemplated. Metal endoluminal stents must be considered experimental until large series validate their use.

Ureteroscopy Injury

Avulsion. Ureteral avulsion during ureteroscopy is treated in the same manner as ureteral injuries after open or laparoscopic surgery, as detailed in the section on ureteral transection.

Perforation. Ureteral perforation during ureteroscopy can be treated by ureteral stenting, usually with no subsequent complications (Flam et al, 1988; Huffman, 1989). The safest approach is to avoid injury by always performing ureteroscopy over a ureteral guidewire and by placing a second ureteral safety wire that is always in place during ureteroscopy and facilitates ureteral stent placement in the presence of problems. We recognize that some expert centers do not use a ureteral guidewire during ureteroscopy and that some no longer use a safety wire (Bratslavsky and Moran, 2004), but we think that at least a safety wire is most prudent for the majority of practitioners.

KEY POINTS: URETERAL TRAUMA

- Ureteral injuries must be carefully sought, or they will be missed.
- After penetrating injury, use CT scan and intraoperative one-shot IVP liberally.
- After penetrating injury, determine the course of the knife or bullet tract to ensure that the ureter is not at risk.
- If delayed recognition is suspected, use CT and retrograde pyelography aggressively.
- Safe ureteroscopy practices should be followed, including using sound technique, limiting ureteroscopy times, using safety wires, scoping over guidewires, and halting ureteroscopy immediately in the face of any ureteral injury.
- Retroperitoneal surgery should be undertaken only with constant attention to the location of the ureter. Intraoperatively, expose and inspect the ureter when necessary.
- See Figure 50-24.

Urinary Lithiasis: Etiology, Epidemiology, and Pathogenesis

Margaret S. Pearle, MD, PhD, Jodi A. Antonelli, MD, and Yair Lotan, MD

Epidemiology of Renal Calculi

Physicochemistry and Pathogenesis

Mineral Metabolism

Pathophysiology of Upper Urinary Tract Calculi

Although stone disease is one of the most common afflictions of modern society, it has been described since antiquity. With Westernization of global culture, however, the site of stone formation has migrated from the lower to the upper urinary tract and the disease once limited to men is increasingly gender blind. Revolutionary advances in the minimally invasive and noninvasive management of stone disease over the past two decades have greatly facilitated the ease with which stones are removed. However, surgical treatments, although they remove the offending stone, do little to alter the course of the disease. Indeed the overall estimated annual expenditure for individuals with insurance claims corresponding to a diagnosis of nephrolithiasis was nearly \$2.1 billion in 2000, reflecting a 50% increase since 1994 (Pearle et al, 2005). Given the frequency with which stones recur, the development of a medical prophylactic program to prevent stone recurrences is desirable. To this end, a thorough understanding of the etiology, epidemiology, and pathogenesis of urinary tract stone disease is necessary.

EPIDEMIOLOGY OF RENAL CALCULI

The lifetime prevalence of kidney stone disease is estimated at 1% to 15%, varying according to age, gender, race, and geographic location. Data from the National Health and Nutrition Examination Survey (NHANES) data sets have demonstrated a linear increase in the prevalence of kidney stones for U.S. adults over the last several decades (Stamatelou et al, 2003), with the most recent prevalence estimate of 8.8% for the period 2007-2010 (Scales et al, 2012).

The rise in kidney stone prevalence is a global phenomenon. Data from five European countries, Japan, and the United States showed that the incidence and prevalence of stone disease has been increasing over time around the world (Romero et al, 2010). In a unique data set derived from a series of nationwide surveys conducted by the Japanese Society on Urolithiasis Research, Yasui and colleagues (2008) found an increase in the age-adjusted annual incidence of first-time stone events from 54.2 per 100,000 in 1965 to 114.3 per 100,000 in 2005. Although the incidence increased in all age groups and in both men and women, the age of peak incidence shifted in men from 20 to 49 years in 1965 to 30 to 69 years in 2005 and in women from 20 to 29 years in 1965 to 50 to 79 years in 2005.

It has been suggested that the rise in stone incidence and prevalence seen in the United States and worldwide can be attributed in part to a rise in the detection of asymptomatic calculi through

increased utilization of radiographic imaging, particularly computed tomography (Boyce et al, 2010; Edvardsson et al, 2013). Edvardsson and colleagues (2013) identified 5945 incident stone formers in the Icelandic population from 1985 to 2008 and found that the annual incidence of stones increased significantly from 108 per 100,000 in the first 5 years of the study to 138 per 100,000 through the remainder of the study interval ($P < .001$). However, they found that the annual incidence of symptomatic stones did not increase significantly, despite significant increases in the incidence of asymptomatic stones in both genders (from 7 to 24 per 100,000 in men, $P < .001$, and from 7 to 21 per 100,000 in women, $P < .001$).

Gender

Historically, stone disease affected adult men more commonly than adult women. By a variety of indicators, including inpatient admissions, outpatient office visits, and emergency department visits, men were affected two to three times more often than women (Soucie et al, 1994; Pearle et al, 2005). However, recent evidence suggests that the difference in incidence between men and women is narrowing. Using the National Inpatient Sample data set representing hospital discharges, Scales and colleagues (2007) found that, although overall population-adjusted discharges for a diagnosis of renal or ureteral calculus increased by only 1.6% from 1997 to 2002, discharges for women increased by 17% while discharges for men decreased by 8.1%. This trend reflects a change in the ratio of male-to-female discharges from 1.7 in 1997 to 1.3 in 2002. Lieske and colleagues (2006) utilized the Rochester Epidemiology Project data (including office, emergency department, and nursing home visits and inpatient and outpatient admissions) to compare the age-adjusted incidence of new symptomatic stone disease from 1970 to 2000 and found similar trends with regard to gender. Although the total rate of symptomatic stone disease for each decade in this time period remained relatively flat ($P = .33$), the rate of symptomatic stones in men declined by 1.7% per year (age-adjusted $P = .019$) but increased in women by 1.9% per year (age-adjusted $P = .064$), resulting in an overall decrease in the male-to-female ratio of symptomatic stones from 3.2 to 1.3 ($P = .006$) during this time period. Another, more contemporary geographic epidemiologic database, the Marshfield Epidemiologic Study Area Database, showed a decline in the male-to-female ratio for urolithiasis from 1.4 in 1992 to 1.0 in 2008 (Penniston et al, 2011).

Using NHANES data, Stamatelou and colleagues (2003) reported a slight decrease in the male-to-female ratio of stone disease, from 1.75 (between 1976 and 1980) to 1.54 (between 1988 and

1994), with the most recent data (2007-2010) revealing a stone prevalence of 10.6% in men and 7.1% in women for a ratio of 1.49, which is only slightly lower than that reported for 1988-1994 (Scales et al, 2012).

Race/Ethnicity

Racial/ethnic differences in the incidence of stone disease have been observed. Among U.S. men, Soucie and colleagues (1994) found the highest prevalence of stone disease in whites, followed by Hispanics, Asians, and African-Americans, who had prevalences of 70%, 63%, and 44% of whites, respectively. Among U.S. women, the prevalence was highest among whites but lowest among Asian women (about half that of whites). According to the most recent NHANES data set, Hispanics (odds ratio [OR] 0.60, 95% confidence interval [CI] 0.49 to 0.73, $P < .001$) and black non-Hispanics (OR 0.37, 95% CI 0.28 to 0.49, $P < .001$) were significantly less likely to report a history of stone disease compared to white non-Hispanics (Scales et al, 2012).

Mente and colleagues (2007) attempted to identify genetic influences on stone disease by comparing stone prevalence among different ethnic groups residing in the same geographic region. Using Europeans (Caucasians) as the reference group, the relative risk of calcium stones was higher in individuals of Arabic (OR 3.8, 95% CI 2.7 to 5.2), West Indian (OR 2.5, 95% CI 1.8 to 3.4), West Asian (OR 2.4, 95% CI 1.7 to 3.4), and Latin American (OR 1.7, 95% CI 1.2 to 2.4) origin and significantly lower in those of East Asian (OR 0.4, 95% CI 0.3 to 0.5) and African (OR 0.7, 95% CI 0.5 to 0.9) descent. Interestingly, despite differences in prevalence of stone disease according to ethnicity, Maloney and colleagues (2005) observed a remarkably similar incidence of metabolic abnormalities between white and nonwhite stone formers from the same geographic region, although the distribution of abnormalities differed, suggesting that dietary and other environmental factors may outweigh the contribution of ethnicity in determining stone risk.

The gender distribution of stone disease varies according to race. Sarmina and colleagues (1987) noted a male-to-female ratio among whites of 2.3 and among African-Americans of 0.65. Michaels and colleagues (1994) also noted a reversal of the male predisposition to stone disease in Hispanics and African-Americans, reporting a male-to-female ratio of 1.8 among Asians, 1.6 among whites, 0.7 among Hispanics, and 0.5 among African-Americans, among a group of patients undergoing shockwave lithotripsy. Dall'era and colleagues (2005) reviewed emergency department records to identify patients presenting with symptomatic renal or ureteral calculi and found a male-to-female ratio of 1.17 among Hispanic patients compared with 2.05 for white patients.

Age

Stone occurrence is relatively uncommon before age 20 but peaks in incidence in the fourth to sixth decades of life (Marshall et al, 1975; Johnson et al, 1979). Lieske and colleagues (2006) found a peak incidence from ages 60 to 69 years in men, but relatively little change in incidence between ages 20 and 70 years for women, with a slightly higher incidence in women 30 to 39 years and 60 to 69 years.

It has been observed that women show a bimodal distribution of stone disease, demonstrating a second peak in incidence in the sixth decade of life corresponding to the onset of menopause and a fall in estrogen levels (Marshall et al, 1975; Johnson et al, 1979). This finding and the lower incidence of stone disease in women compared with men have been attributed to the protective effect of estrogen against stone formation in premenopausal women, owing to enhanced renal calcium absorption and reduced bone resorption (McKane et al, 1995; Nordin et al, 1999). Indeed, Heller and colleagues (2002) identified lower urinary saturation of calcium oxalate and brushite in women compared with men. Moreover, urinary calcium was lower in women than in men until beyond age 50, when it reached equivalence in the two groups. Estrogen-treated

postmenopausal women had lower urinary calcium and saturation of calcium oxalate than untreated women.

Fan and colleagues (1999) found that androgens increased and estrogens decreased urinary and serum oxalate in an experimental rat model, perhaps accounting for the reduced risk of stone formation in women. However, van Aswegen and colleagues (1989) found lower levels of urinary testosterone in stone formers compared with non-stone-forming control subjects, further confounding the issue.

Geography

The geographic distribution of stone disease tends to roughly follow environmental risk factors; a higher prevalence of stone disease is found in hot, arid, or dry climates such as the mountains, desert, or tropical areas. However, genetic factors and dietary influences may outweigh the effects of geography. Finlayson (1974) reviewed several worldwide geographic surveys and found that areas of high stone prevalence included the United States, the British Isles, Scandinavian and Mediterranean countries, northern India and Pakistan, northern Australia, Central Europe, portions of the Malay peninsula, and China. Within the United States, Mandel and Mandel (1989a, 1989b) identified the highest rates of hospital discharges for patients with calcium oxalate stones in the Southeast and for uric acid stones in the East, among the veteran patient population (Fig. 51-1). Soucie and colleagues (1994) found increasing age-adjusted prevalence rates in both men and women going from north to south and west to east, with the highest prevalence observed in the Southeast. After controlling for other risk factors, the authors determined that ambient temperature and sunlight were independently associated with stone prevalence (Soucie et al, 1996).

Climate

Seasonal variation in stone disease is likely related to temperature by way of fluid losses from perspiration and perhaps by sunlight-induced increases in vitamin D. Prince and Scardino (1960) noted the highest incidence of stone disease in the summer months, July through September, with the peak occurring within 1 to 2 months of maximal mean temperatures (Prince et al, 1956). Using data obtained from the Taiwan National Health Insurance Research Database (1999-2003), Chen and colleagues (2008) analyzed

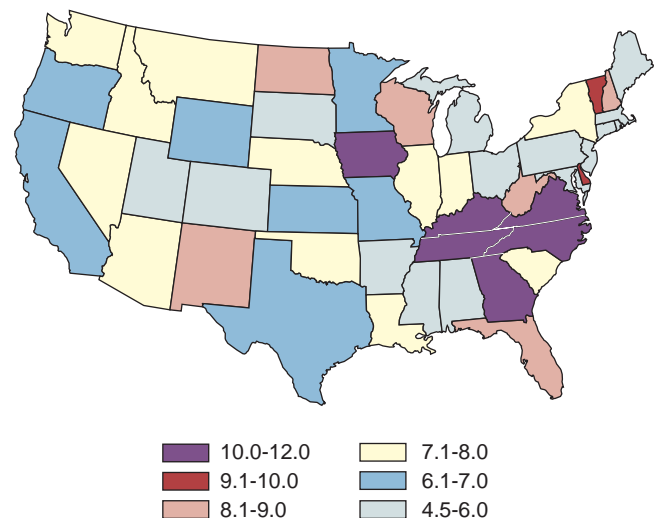

Figure 51-1. Geographic distribution of urinary tract stone disease in the U.S. veteran population from 1983 to 1986. Data are expressed as urinary tract stone patients per 1000 hospital discharges. (From Mandel NS, Mandel GS. Urinary tract stone disease in the United States veteran population: II. Geographical analysis of variations in composition. *J Urol* 1989;142:1516.)

monthly inpatient and outpatient medical benefit claims for a primary diagnosis of renal or ureteral calculi or renal colic and found that the peak incidence of stone-related claims occurred in July through September, with a sharp decline in claims in October. Ambient temperature, atmospheric pressure, and hours of sunshine all correlated with monthly stone-related claims, but after adjusting for seasonality, month, and trend, ambient temperature was found to be the most important determinant of stone-related events.

The study of military personnel translocated to desert locations has provided a unique opportunity to study the effect of climate on a defined population. [Pierce and Bloom \(1945\)](#) reported that American soldiers in an undisclosed desert location had an increase in symptomatic episodes of renal colic during the summer season. Another study of military personnel who developed symptomatic stones after arrival in Kuwait and Iraq revealed a mean time interval to stone formation of 93 days ([Evans and Costabile, 2005](#)). Finally, [Parry and Lister \(1975\)](#) measured urinary calcium and magnesium levels in soldiers before and 10 days after transfer to the Persian Gulf and noted increased urinary calcium levels from baseline in those soldiers transferred during the summer months but not among those transferred during the “cold season,” which was attributed to sunlight-induced increased production of 1,25-dihydroxyvitamin D₃ (1,25[OH]₂D₃). Thus it is likely that climate and geography influence the prevalence of stone disease indirectly, through effects on temperature and possibly sunlight.

[Brikowski and colleagues \(2008\)](#) constructed two alternate models describing the temperature dependence of stone disease on the basis of reported regional stone prevalence rates and corresponding mean annual temperatures in order to predict the anticipated change in stone prevalence resulting from global warming. Prevalence rates obtained from the Second Cancer Prevention Survey of 1982 ([Soucie et al, 1996](#)) were consistent with a nonlinear, or peaked, relationship between temperature and stone prevalence, while a data set from the Veterans Administration that was analyzed by the Urologic Diseases in America project ([Pearle et al, 2005](#)) more closely approximated a linear fit. Using a moderate-severity warming model to predict temperature change resulting from global warming in the United States, the authors estimated an increase of 1 to 1.5 million lifetime cases of climate-related nephrolithiasis by 2050. According to the linear model of temperature dependence, the net effect of warming will be a northward expansion of the current-day “stone belt” (which occupies primarily the Southeast part of the United States) into the Midwest, such that by 2050 it will occupy the entire southeastern portion of the country and all of California. The nonlinear model predicts that the zone of elevated stone risk currently located in the Southeast will expand northward to include a band of states from Kansas to Virginia and Northern California, but with the increase in prevalence primarily concentrated south of the temperature threshold.

[Fakheri and Goldfarb \(2009\)](#) later revisited the analysis correlating mean annual temperature and stone prevalence and confirmed that temperature positively correlated with rate of stone prevalence. However, they further established that the temperature dependence of stone disease could be attributed primarily to an effect on men. For every unit degree Fahrenheit increase in temperature, the percent prevalence rate increased by 0.15 ($R^2 = 0.37$) in men and 0.04 ($R^2 = 0.51$) in women. The pathophysiology responsible for these gender-based differences in response to temperature has not been elucidated to date but is likely affected by confounders such as differential sunlight exposure, occupation, and hydration status.

Occupation

Heat exposure and dehydration constitute occupational risk factors for stone disease as well. Cooks and engineering room personnel, both of whom are exposed to high temperatures, were found to have the highest rates of stone formation among personnel of the Royal Navy ([Blacklock, 1969](#)). Likewise, [Atan and colleagues \(2005\)](#) found a significantly higher incidence of stones among steelworkers exposed to high temperatures (8%) compared with those working in normal temperatures (0.9%). Metabolic evaluation of these two

groups of workers showed a higher incidence of low urine volume and hypocitraturia among the workers in the hot area. [Borghi and colleagues \(1993\)](#) also noted differences in the incidence of stone disease and urinary stone risk factors between workers at a glass plant who were or were not chronically exposed to high temperatures causing massive perspiration. Those exposed to high temperatures exhibited lower urine volumes and pH, higher uric acid levels, and higher urine specific gravity, leading to higher urinary saturation of uric acid. Accordingly, those workers who formed stones had a remarkably high incidence of uric acid stones (38%).

Individuals with sedentary occupations such as those in managerial or professional positions have been found to carry an increased risk of stone formation for unclear reasons ([Blacklock, 1969](#)). This finding is consistent with the work of [Robertson and colleagues \(1980\)](#), who reported an increased risk of stone disease in affluent individuals, countries, and societies, which may be reflective of a more indulgent diet and lifestyle.

Obesity, Diabetes, and Metabolic Syndrome

The association of body size and incidence of stone disease has been extensively investigated. In two large prospective cohort studies of men and women, the prevalence and incident risk of stone disease were directly correlated with weight and body mass index (BMI) in both sexes, although the magnitude of the association was greater in women than in men ([Curhan et al, 1998](#); [Taylor et al, 2005b](#)). Although these investigators identified a reduced risk of incident stone formation with high fluid intake (men and women) and low protein intake (men) ([Curhan et al, 1993, 1997](#)), they found that obesity and weight gain were independent risk factors for incident stone formation that could not be accounted for by diet alone ([Taylor et al, 2005b](#)). [Nowfar and colleagues \(2011\)](#) utilized a large all-payer inpatient care database and likewise found an increased risk of stones with obesity that was more pronounced in women than men. Finally, [Semins and coworkers \(2010\)](#), using claims data, found an increasing risk of kidney stones with increasing BMI, up to a BMI of 30 kg/m², at which point the risk stabilized.

The constellation of visceral obesity along with hyperlipidemia, hypertriglyceridemia, hyperglycemia, and/or hypertension, known as metabolic syndrome, has also been linked to an increased risk for kidney stones. Utilizing the NHANES III (1988-1994) data set, [West and colleagues \(2008\)](#) found that those with a diagnosis of metabolic syndrome were significantly more likely to report a history of kidney stones compared to healthy subjects (8.8% vs. 4.3%, respectively, $P < .001$). Furthermore, they found that the prevalence of a self-reported history of kidney stones increased with the number of metabolic syndrome traits, with the prevalence of kidney stones estimated at 3% for no traits, 7.5% for three traits, and 9.8% for five traits. Multivariate analysis revealed that the presence of four or five metabolic syndrome traits was associated with a more than twofold increase in the odds of a self-reported stone history (OR 2.42, 95% CI 1.57 to 3.73). [Jeong and colleagues \(2011\)](#) corroborated these findings in a large, healthy screened population in Asia.

Metabolic syndrome has been implicated as a potential precursor of type 2 diabetes mellitus. [Taylor and colleagues \(2005a\)](#) prospectively studied the association between diabetes and incident kidney stones in three large cohorts (Nurses' Health Study I [NHS I], composed of older women; Nurses' Health Study II [NHS II], composed of younger women; and the Health Professionals Follow-Up Study [HPFS], composed of men) and found that, after adjusting for BMI, diet, and thiazide use, a history of diabetes was associated with an increase in incident kidney stones in women but not men. Conversely, a history of kidney stones was associated with an increase in the incidence of self-reported diabetes for both women and men (OR 1.33, 95% CI 1.18 to 1.50 for older women; OR 1.48, 95% CI 1.14 to 1.91 for younger women; and OR 1.49, 95% CI 1.29 to 1.72 for men). In addition, in a prospective study from Taiwan, [Chung and coworkers \(2011\)](#) observed a 1.3-fold higher likelihood of being diagnosed with diabetes in a group of

individuals within 5 years of a diagnosis of kidney stones than in a comparison cohort of individuals who did not form stones (95% CI 1.26 to 1.39, $P < .001$). Stone formers with type 2 diabetes have been shown to have higher urinary oxalate and lower urine pH than nondiabetic stone formers (Eisner et al, 2010a).

While the association between obesity, diabetes, and metabolic syndrome has been explored in the epidemiologic literature, the exact pathophysiologic mechanism responsible for this association has yet to be completely defined; however, a central theme of these comorbidities is a metabolic state of insulin resistance. Evidence linking obesity and insulin resistance with low urine pH and uric acid stones (Maalouf et al, 2004a, 2004b), as well as an association between hyperinsulinemia and hypercalciuria (Kerstetter et al, 1991; Shimamoto et al, 1995; Nowicki et al, 1998), could account for an increased risk of uric acid and/or calcium stones in obese patients. A study of stone-forming and non-stone-forming participants in the HPFS (599 stone-forming and 404 non-stone-forming men), NHS I (888 stone-forming and 398 non-stone-forming older women), and NHS II (689 stone-forming and 295 non-stone-forming younger women) for whom 24-hour urine studies were collected correlated urinary stone risk profiles with BMI (Taylor and Curhan, 2006). Subjects with higher BMI excreted more urinary oxalate, uric acid, sodium, and phosphorus than those with lower BMI. Furthermore, similar to other studies, urinary supersaturation of uric acid increased with BMI.

It has been suggested that the association of obesity with calcium oxalate stone formation is primarily due to increased excretion of promoters of stone formation (Siener et al, 2004; Negri et al, 2007). In contrast, the association of obesity and uric acid stone formation is primarily influenced by urinary pH.

Cardiovascular Disease

A number of investigators have explored the association between hypertension and kidney stones. Analysis of data from the HPFS and NHS I found that a history of nephrolithiasis was associated with an increased risk of developing hypertension (Madore et al, 1998a, 1998b), an association that was shown to be strongest among overweight female stone formers (Gillen et al, 2005). Increased dietary intake of substances associated with both hypertension and stone disease, including calcium, sodium, and potassium, has been proposed as a possible explanation for this finding. Borghi and colleagues (1999) observed higher urinary calcium, uric acid, and oxalate and supersaturation of calcium oxalate in men and women with hypertension compared to normotensive individuals. In another study, hypertensive stone formers were found to excrete about 25 mg/day more calcium than normotensive stone formers (Eisner et al, 2010b).

Stone disease has also been linked to heart disease. One longitudinal study found a 31% higher incidence of myocardial infarction among those with a history of kidney stones compared to those without stones, even after adjusting for comorbidities, including chronic kidney disease (Rule et al, 2010). In addition, Reiner and coworkers (2011) documented an association between history of kidney stones and subclinical carotid atherosclerosis in young men and women. Finally, Ferraro and colleagues (2013b) explored the association between kidney stones and risk of heart disease in three large cohort studies, NHS I, NHS II, and HPFS, and found that a history of kidney stones was associated with a modest but significant increase in heart disease in both female cohorts but not in the male cohort. The etiology of this gender difference has not been elucidated.

Water

The beneficial effect of a high fluid intake on stone prevention has long been recognized. In two large observational studies, fluid intake was found to be inversely related to the risk of incident kidney stone formation (Curhan et al, 1993, 1997). Furthermore, in a prospective, randomized trial assessing the effect of fluid intake on stone recurrence among first-time idiopathic calcium stone

formers, urine volume was significantly higher in the group assigned to a high fluid intake compared with the control group receiving no recommendations, and, accordingly, stone recurrence rates were significantly lower (12% vs. 27%, respectively) (Borghi et al, 1996).

Geographic differences in the incidence of stone disease have been ascribed in some cases to differences in the mineral and electrolyte content of water in different areas. Although several investigators reported a lower incidence of stone disease in geographic regions with a “hard” water supply compared with a “soft” water supply, where water “hardness” is determined by content of calcium carbonate (Churchill et al, 1978; Sierakowski et al, 1979), others found no difference. Schwartz and colleagues (2002) found no association between water hardness and incidence of stone episodes, although they did observe a correlation between water hardness and urinary magnesium, calcium, and citrate levels.

KEY POINTS: EPIDEMIOLOGY

- Upper urinary tract stones occur more commonly in men than women, but there is evidence that the gender gap is narrowing.
- Whites have the highest incidence of upper tract stones compared with Asians, Hispanics, and African-Americans.
- Prevalence of stone disease shows geographic variability, with the highest prevalence of stone disease in the Southeast.
- The risk of stone disease correlates with weight and BMI.
- Stone disease has been correlated with a number of systemic disorders, including diabetes, metabolic syndrome, and cardiovascular disease.

PHYSICOCHEMISTRY AND PATHOGENESIS

The physical process of stone formation comprises a complex cascade of events that occurs as the glomerular filtrate traverses the nephron. It begins with urine that becomes supersaturated with respect to stone-forming salts, such that dissolved ions or molecules precipitate out of solution and form crystals or nuclei. Once formed, crystals may flow out with the urine or become retained in the kidney at anchoring sites that promote growth and aggregation, ultimately leading to stone formation. The discussion that follows describes the process of stone formation from a physicochemical standpoint.

State of Saturation

A solution containing ions or molecules of a sparingly soluble salt is described by the *concentration product*, which is a mathematic expression of the product of the concentrations of the pure chemical components (ions or molecules) of the salt. For example, the concentration product (CP) expression for sodium chloride is $CP = [Na^+][Cl^-]$. A pure aqueous solution of a salt is considered *saturated* when it reaches the point at which no further added salt crystals will dissolve. The concentration product at the point of saturation is called the *thermodynamic solubility product* (K_{sp}), which is the point at which the dissolved and crystalline components are in equilibrium for a specific set of conditions. At this point, addition of further crystals to the saturated solution will cause the crystals to precipitate unless the conditions of the solution, such as pH or temperature, are changed.

In urine, despite concentration products of stone-forming salt components such as calcium oxalate that exceed the solubility product, crystallization does not necessarily occur because of the presence of inhibitors and other molecules that allow higher concentrations of calcium oxalate to be held in solution before precipitation or crystallization occurs. In this state of saturation, urine is considered to be *metastable* with respect to the salt. As concentrations of the salt increase further, the point at which it can no

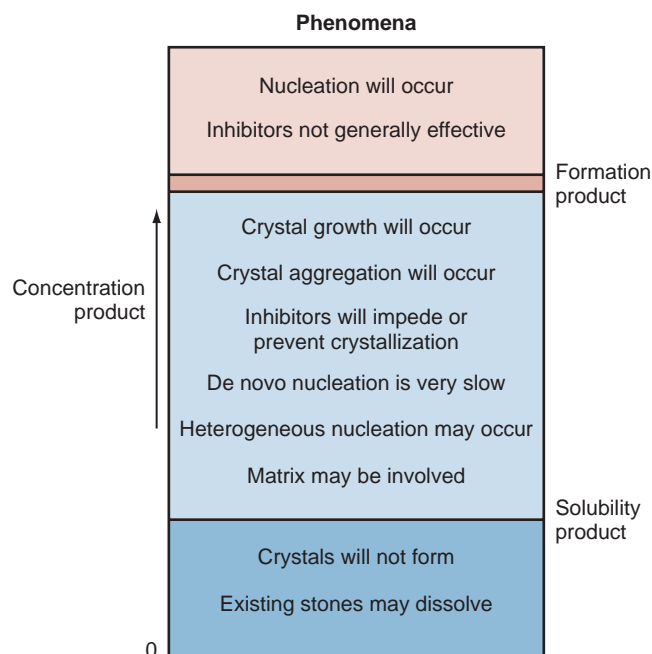

Figure 51-2. States of saturation. Listed are solid-solution phenomena that are likely to occur at a given range of concentration products. Three general situations are considered: (1) concentrations less than the solubility product (undersaturation), (2) concentrations that are metastable with respect to de novo precipitation (between the solubility product and the formation product), and (3) concentrations that are greater than the formation product (unstable). (From Meyer JL. *Physicochemistry of stone formation*. In: Resnick MI, Pak CYC, editors. *Urolithiasis: a medical and surgical reference*. Philadelphia: Saunders; 1990. p. 11–34.)

longer be held in solution is reached and crystals form. The concentration product at this point is called the *formation product* (K_f).

The solubility product and the formation product differentiate the three major states of saturation in urine: undersaturated, metastable, and unstable (Fig. 51-2). Below the solubility product, crystals will not form under any circumstances and dissolution of crystals is theoretically possible. At concentrations above the formation product, the solution is unstable and crystals will form. In the metastable range between the solubility product and the formation product, in which the concentration products of most common stone components reside, spontaneous nucleation or precipitation does not occur despite urine that is supersaturated. It is in this area that modulation of factors controlling stone formation can take place and therapeutic intervention is directed.

In the metastable range of concentration products, although crystal growth can occur on existing crystals, de novo formation of crystals cannot occur in the length of time it normally takes for the filtered urine to reach the bladder. However, crystal formation can occur in this range under certain circumstances. First, in parts of the nephron local concentration products may exceed the formation product for long enough time periods to allow nucleation to occur. Second, local areas of obstruction or stasis in the upper urinary tract may prolong urinary transit time and allow crystal formation to occur in metastable urine. Finally, microscopic impurities or other constituents in the urine can facilitate the nucleation process by adsorption of the crystal components in a geometric way that resembles the native crystal. The energy required for this “heterogeneous nucleation” process is much less than that required for “homogeneous nucleation.”

To estimate the state of saturation for any given crystal system such as calcium oxalate or calcium phosphate, Pak and Chu (1973) developed a mathematic formula, the *activity product ratio*, that takes into account urine pH and the ionic activities of all major ion

species directly involved in the stone-forming process or those that affect the overall ionic strength of the urine. Finlayson subsequently developed a computer program, EQUIL 2, to measure the state of saturation, which is commonly used today (Werness et al, 1985). The *relative saturation ratio* (RSR) or *concentration product ratio* (CPR) is defined as the ratio of the concentration product of the urine to the solubility product of the specified stone-forming salt. A reduction in the numerator will lead to undersaturation of the urine with respect to the stone-forming salt and consequently reduce the likelihood of precipitation. Thus, at RSR values less than 1, crystals will dissolve; at RSR values greater than 1, crystals will form and grow. Reducing the RSR can be accomplished by reducing the urinary concentrations of the stone components (e.g., calcium or oxalate) by reducing the filtered load or by increasing urinary reabsorption. In addition, complexation with substances such as citrate reduce available free ionic calcium and decrease the RSR. On the other hand, manipulation of factors such as pH can significantly impact the concentration of ions such as phosphate, the generation of which is highly pH dependent. Manipulation of pH has little effect on oxalate concentration, however, because oxalic acid is a strong acid ($pK = 4$) and pH changes within the physiologic range will have little effect on oxalate concentration.

Rodgers and colleagues (2006) introduced another computer program, JESS (Joint Expert Speciation System), to calculate urinary saturation of stone-forming salts as an estimate of the propensity for stone formation, thereby challenging the accuracy of the widely accepted EQUIL 2 computer program. The JESS program recognizes several soluble complexes not taken into account by EQUIL 2, including dicalcium-dihydrogen phosphate and calcium phosphocitrate, whose formation depends on pH and citrate. Consequently, the fraction of ionized calcium, phosphate, and oxalate estimated by JESS will be lower than that estimated by EQUIL 2. In order to resolve the discrepancy between the two programs, the supersaturation index (SI) according to JESS and the RSR according to EQUIL 2 were compared with experimentally determined urinary saturation of brushite (Pak et al, 2009b) and calcium oxalate (Pak et al, 2009a). The experimentally determined method measures the CPR without using computer-derived ionic activities. By determining the concentration product before and after incubation with a synthetic stone-forming salt, this method directly estimates saturation by measuring the extent of stone growth (in a supersaturated solution) or dissolution (in an undersaturated solution). No significant difference was found between experimentally determined CPR and JESS-derived SI, for either brushite or calcium oxalate. However, EQUIL 2–derived RSR was consistently and significantly higher than both CPR and SI, overestimating CPR by about 80% for brushite and 50% for calcium oxalate. **Because CPR is too labor intensive for routine use, SI according to JESS probably provides a more reliable estimation of urinary saturation than RSR derived from EQUIL 2.**

Historically, urinary oxalate has been considered a more important contributor to calcium oxalate stone formation than urinary calcium, because a rise in urinary calcium concentration impacted urinary saturation of calcium oxalate less than a rise in oxalate concentration (Nordin et al, 1972; Robertson and Peacock, 1980). Furthermore, at high urinary calcium concentrations the saturation of calcium oxalate reached a plateau that did not exceed the theoretic formation product of calcium oxalate, whereas high oxalate concentrations did, thereby increasing the risk of calcium oxalate crystal formation. Pak and colleagues (2004), however, challenged the notion that urinary oxalate exerts a greater pathogenetic effect than calcium in calcium oxalate stone formation. They demonstrated that the choice of stability constant used for calculating the RSR determines the relative effects of urinary calcium and oxalate concentration. Using the commonly accepted stability constant of 2.746×10^3 (used in the EQUIL 2 program), the effect of urinary calcium and oxalate proved to be equivalent. Thus they concluded that **urinary calcium and oxalate are both important and equal contributors to calcium oxalate stone formation**. As such, reduction in both calcium and oxalate will be effective in reducing the RSR, and intervention to prevent stone formation can be directed

at either. When these studies were repeated using JESS, the same finding of an equivalent effect of calcium and oxalate on urinary SI of calcium oxalate was found, although the dependence of SI on calcium and oxalate was less marked than was demonstrated for RSR (Pak et al, 2009a).

Nucleation and Crystal Growth, Aggregation, and Retention

In normal human urine, the concentration of calcium oxalate is four times higher than its solubility in water. Urinary factors favoring stone formation include low volume and citrate, while increased calcium, oxalate, phosphate, and uric acid all increase calcium oxalate supersaturation. Once the concentration product of calcium oxalate exceeds the solubility product, crystallization can potentially occur. However, in the presence of urinary inhibitors and other substances, calcium oxalate precipitation occurs only when supersaturation exceeds solubility by 7 to 11 times.

Homogeneous nucleation is the process by which nuclei form in pure solution. Nuclei are the earliest crystal structures that will not dissolve. Small nuclei are unstable; below a critical size threshold, dissolution of the crystal is favored over crystal growth. If the driving force (supersaturation level) and the stability of the nuclei are adequate and the lag time to nucleation is sufficiently short compared with the transit time of urine through the nephron, the nuclei will persist. Inhibitors, such as citrate, destabilize nuclei, whereas promoters stabilize nuclei by providing a surface with a binding site that accommodates the crystal structure of the nucleus. In urine, crystal nuclei usually form through heterogeneous nucleation by adsorption onto existing surfaces of epithelial cells (Umekawa et al, 2001), cell debris (Fasano and Khan, 2001), or other crystals (Kok, 1997).

Within the timeframe of transit of urine through the nephron, estimated at 5 to 7 minutes, crystals cannot grow to reach a size sufficient to occlude the tubular lumen. However, if enough nuclei form and grow, aggregation of the crystals will form larger particles within minutes that can occlude the tubular lumen. Inhibitors can prevent the process of crystal growth or aggregation. Magnesium and citrate inhibit crystal aggregation. Nephrocalcin, an acidic glycoprotein made in the kidney, inhibits calcium oxalate nucleation, growth, and aggregation (Nakagawa et al, 1987; Asplin et al, 1991). Tamm-Horsfall mucoprotein, the most abundant protein in urine, inhibits aggregation (Hess et al, 1991), and uropontin inhibits crystal growth (Shiraga et al, 1992). Bikunin, the light chain of inter- α -trypsin, has been shown to be an efficient inhibitor of crystal nucleation and aggregation.

Opposing views regarding the formation and growth of crystal particles have led to controversy over the concept of free crystal particle growth versus fixed particle growth. Although it was initially concluded that free particle stone formation was impossible within the normal transit time through the nephron (Finlayson and Reid, 1978), later recalculation using current nephron dimensions, supersaturation, and crystal growth rates determined that crystalline particles can be formed that are large enough to be retained during normal transit time through the kidney (Kok and Khan, 1994).

Fixed particle growth theory presupposes an anchoring site to which crystals bind, thereby prolonging the time the crystals are exposed to supersaturated urine and facilitating crystal growth and aggregation. A number of mechanisms have been proposed to account for crystal fixation. One favored theory proposes that oxalate-induced injury to renal tubular epithelial cells promotes adherence of calcium oxalate crystals (Miller et al, 2000). In animal models of stone formation in which administration of high oxalate loads leads to calcium oxalate crystal formation, elevated urinary levels of enzyme markers of cell injury, including *N*-acetyl- β -glucosidase and alkaline phosphatase, provide evidence of damage to renal tubular epithelial cells (Khan et al, 1992; Thamilselvan and Khan, 1998). Oxalate-induced cell injury is thought to be mediated by way of reactive oxygen species (Thamilselvan and Khan, 1998; Thamilselvan et al, 1999). Not only are high concentrations of oxalate toxic to renal tubular cells, but calcium oxalate crystals themselves have also been shown to promote damage to cells (Khan

et al, 1993, 1999; Thamilselvan and Khan, 1998; Thamilselvan et al, 1999). Davalos and colleagues (2010) demonstrated in cell culture that calcium oxalate monohydrate crystals induced oxidative stress to renal tubular epithelial cells, leading to eventual apoptosis through pathways that have yet to be defined. Furthermore, they showed that *N*-acetylcysteine, a potent antioxidant, effectively neutralized this cytotoxicity and allowed for retention of renal cell integrity. Asselman and coworkers (2003) used ethylene glycol to induce hyperoxaluria in rats and showed that calcium oxalate adherence occurred only to injured renal cells. Additionally, they showed that markers of kidney injury and inflammation, including hyaluronan, osteopontin, and cell surface receptor CD44, were preferentially expressed at times of crystal adherence.

In addition to these findings in animal models and in vitro systems, Holoch and Tracy (2011) demonstrated an association between antioxidants and stone disease in human patients. Significantly lower levels of serum antioxidants (α -carotene, β -carotene, and β -cryptoxanthin) were found in those who reported a history of stones than in non-stone-forming controls, suggesting that higher levels of antioxidants may confer protection from stone formation. Of note, in vivo evidence for oxalate-induced tubular damage in humans has been lacking. Indeed, no increase in markers of oxidative stress or renal cell injury has been observed in normal individuals or stone formers after ingestion of a large oxalate load (Knight et al, 2007).

Oxidative stress has been implicated as a pathophysiologic mechanism to explain the epidemiologic associations that have been demonstrated between diabetes, metabolic syndrome, and coronary heart disease (Khan, 2012). Furthermore, Yoshioka and colleagues (2010) suggested that the gender disparity historically seen in stone disease may be attributed to differential antioxidant production associated with testosterone and estradiol. They found in a rat model that increased testosterone was associated with increased oxidative stress and stones, while increased levels of estradiol suppressed both of these parameters.

How oxalate-induced renal tubular cell damage potentially promotes crystal retention is not known. Randall (1937) first observed areas of damage associated with subepithelial plaques on the renal papillae. Later, structural analyses in hyperoxaluric rats demonstrated crystals attached to the injured epithelium lining the collecting ducts (Khan, 1991). In vitro studies confirmed increased binding of calcium oxalate crystals to injured renal epithelial cells in culture (Verkoelen et al, 1998). Whether the renal tubular cells or the interstitium constitutes the primary site of stone formation is unclear. Evidence of endocytosis of calcium oxalate crystals into renal tubular cells has been demonstrated in patients with disorders of oxalate metabolism (Saxon et al, 1974; Mandell et al, 1980; Lieske et al, 1992). Intracellular incorporation of these crystals could potentially lead to cell death and deposition of crystals in the interstitium, or transport of the crystals from the lumen to the basement membrane side could promote cell damage and subsequent erosion through to the papillary surface. Knoll and colleagues (2004) demonstrated in cell culture that oxalate-induced damage was more pronounced in renal nontubular compared with tubular cell lines and, further, that renal epithelial cells were more vulnerable to the toxic effects of oxalate on their basolateral side compared with their apical (luminal) side, implicating the interstitium as a possible site of primary stone formation.

In light of these findings, a number of investigators have revisited the role of Randall plaques in the pathogenesis of stone formation. Low and Stoller (1997) mapped the papillae of patients undergoing endoscopic stone removal, as well as control subjects undergoing endoscopy for unrelated reasons, and found that papillary plaques occurred in 74% of stone formers compared with only 43% of control subjects. Stoller and colleagues (2004) hypothesized that the inciting event in the pathogenesis of stones may be vascular injury to the vasa recta near the renal papilla. Repair of damaged vessel walls could involve an atherosclerotic-like reaction that results in calcification of the endothelial wall, followed by erosion into the papillary interstitium and then into the collecting ducts, where it could serve as a nidus for stone formation.

Figure 51-3. Endoscopic (A) and histologic (B) images of Randall plaques in calcium oxalate patients. A, Sites of Randall plaques (arrows) appear as irregular white areas beneath the urothelium. B, A low-magnification light-microscopic image of a papillary biopsy specimen. Sites of calcium deposits were stained black by the Yasue metal substitution method for calcium histochemistry. (From Evan AP, Lingeman JE, Coe FL, et al. Randall's plaque of patients with nephrolithiasis begins in basement membranes of thin loops of Henle. *J Clin Invest* 2003;111:607–16.)

Evan and colleagues (2003) presented an alternative view of the pathogenesis of stone formation on the basis of extensive analysis of papillary plaques derived from biopsies obtained during percutaneous nephrolithotomy in idiopathic calcium oxalate stone formers. They localized the origin of the plaque to the basement membrane of the thin limbs of the loops of Henle and demonstrated that the plaque subsequently extends through the medullary interstitium to a subepithelial location (Fig. 51-3). Once the plaque erodes through the urothelium, it is thought to constitute a stable, anchored surface on which calcium oxalate crystals can nucleate and grow as attached stones. The origin of the crystals that initiate the plaque at the basement membrane of the thin loop of Henle is unclear; however, they do not appear to come from the renal tubular cells or lumen (Evan et al, 2003). One theory suggests that these crystals arise *de novo* by high concentrations of calcium oxalate inducing local inflammation that triggers phenotypic differentiation of tubular epithelial cells into mesenchymal cells with osteogenic activity (Gambaro et al, 2008). Support for this hypothesis comes from the fact that bone osteoid proteins, including osteopontin and osteocalcin, have been found in the plaques.

Among idiopathic calcium oxalate stone formers, the volume of papillary surface covered by plaque was shown to correlate negatively with urine volume and positively with hypercalciuria (Kuo et al, 2003a, 2003b) and the number of stones formed (Kim et al, 2005), providing further corroborating clinical evidence for this sequence of events. Furthermore, Matlaga and colleagues (2006) observed that in approximately half of a studied cohort of calcium oxalate stone formers the stones were observed to be attached to the renal papillae, suggesting that formation of attached stones is an early step in the process of stone formation. Miller and coworkers (2009) further substantiated this hypothesis by endoscopically imaging and recording the details of stone location for nine idiopathic hypercalciuric stone formers undergoing percutaneous neph-

rolithotomy or ureteroscopy. They observed that 90 of 115 stones were attached to papillae and 81 of the 90 attached stones were visually confirmed to be attached specifically to plaque. Furthermore, among 25 stones that were not attached to papillae, evidence from micro-computed tomographic analysis suggested that they originated on interstitial plaques (Miller et al, 2010). These findings support the hypothesis that growth on plaque is the primary mechanism of stone growth for idiopathic calcium stone formers.

Using high-resolution Fourier transform infrared microspectroscopy and electron diffraction, the crystal component of plaque was determined to be calcium apatite (Evan et al, 2003). Further analysis revealed that the deposits consisted of individual laminated particles with mineral and organic layers. All crystals were coated with organic material, and osteopontin was identified on the outer surface of the crystal at the junction of the overlying organic molecular layer, potentially implicating osteopontin in plaque biology (Evan et al, 2005). Daudon and colleagues (2007) analyzed more than 5000 stones associated with plaque and found that carbapatite constituted the main component of the plaque in nearly all cases.

One intriguing but unproven hypothesis for the origin of the calcium phosphate particles described earlier involves nanobacteria, or calcifying nanoparticles (CNPs), which are self-propagating entities that precipitate calcium apatite on their exterior membrane but for which to date no genomic material has been identified (Kajander and Ciftcioglu, 1998). Although the existence of these particles has been questioned (Cisar et al, 2000), several lines of evidence support a role of CNPs in stone formation (Kajander et al, 2001). CNPs have been detected in blood, blood products, and kidney stones, as well as in other pathologic calcifications (Ciftcioglu et al, 1999, 2006). They have been shown to promote rapid precipitation of calcium phosphate from blood under physiologically unfavorable conditions (Kajander and Ciftcioglu, 1998), and in an

animal model intrarenal injection of CNP was shown to induce renal calcification (García Cuerpo et al, 2000). In a recent study in which renal papillary and blood samples were obtained from human patients undergoing nephrectomy, immunohistochemical staining using anti-CNP antibodies was positive in 8 of 11 papillary samples in which Randall plaques were visualized and in only one of those in which they were not (Ciftçioğlu et al, 2008). In addition, 12 of 14 samples positive for CNP-like spheres on scanning electron microscopy demonstrated CNP growth in culture, compared with only one of three scanning electron microscopy-negative samples. Although not necessarily causative, these findings loosely suggest an association between CNP and Randall plaque. CNPs have also been associated with cardiovascular calcification and atherosclerotic disease (Shiekh et al, 2009) and have been implicated in endothelial damage of blood vessels causing subsequent calcification, perhaps providing a common pathogenetic link for CNP involvement in stone formation.

The pathogenesis of stone formation in other calcium stone formers and in noncalcium stone formers may differ from that of typical idiopathic calcium oxalate stone formers. Indeed, distinct morphologic subtypes characterizing particular patient phenotypes have been found, consistent with divergent underlying pathophysiologic abnormalities. Unlike idiopathic calcium oxalate stone formers, patients with enteric hyperoxaluria resulting from intestinal bypass for obesity demonstrate no plaque but instead show apatite crystal deposits plugging the inner medullary collecting duct lumens, along with associated epithelial cell damage with interstitial inflammation and fibrosis (Fig. 51-4) (Evan et al, 2003). Interestingly, despite the acidic urine typically found in these patients, the crystal deposits are composed of apatite, which is generally unstable at low urine pH, suggesting discordance between local tubular pH and final urinary pH (Evan et al, 2006a).

Brushite stone formers have been found to have pathology intermediate between idiopathic calcium oxalate stone formers and intestinal bypass patients, demonstrating interstitial apatite plaque and apatite plugging of the inner medullary and terminal collecting ducts, along with associated collecting duct injury and

interstitial fibrosis (Fig. 51-5) (Evan et al, 2005). The pathogenesis of brushite stones has been postulated by Evan and colleagues (2005) to occur by way of crystallization of apatite in the collecting ducts leading to collecting duct injury, cell death, and enlargement of collecting ducts. Interstitial inflammation in response to the injured cells may lead finally to progressive involvement of adjacent renal tissue. Observing a recent increase in the incidence of brushite stones, Krambeck and colleagues (2010) hypothesized that some brushite stones may begin as calcium oxalate stones after an initial insult incites plaque formation. Further insult, perhaps caused by infection or shockwave lithotripsy, then leads to tubular dysfunction causing an alkaline environment, inflammation, and intraductal hyaluronic acid deposition, ultimately promoting a transition to brushite stones.

With distal renal tubular acidosis (RTA), patients typically exhibit extensive renal calcifications. In a subgroup of patients with distal RTA in whom most of the calcifications were surgically removable, endoscopic inspection of the renal papillae demonstrated a variety of findings (Evan et al, 2007). In some patients minimal papillary changes were observed, whereas in others the papillae were pitted and contained calcium phosphate plugs protruding from dilated collecting ducts with extensive surrounding fibrosis. Randall plaques were rarely encountered. In contrast, patients with primary hyperparathyroidism display histologic features of brushite stone formers, including plugging of ducts of Bellini and inner medullary collecting ducts, but also display interstitial deposits of plaque and associated stone overgrowth traditionally seen with idiopathic calcium oxalate stone formers (Evan et al, 2008).

Finally, although patients with cystinuria were found to have plugging of the terminal collecting ducts of Bellini with masses of cystine crystals, surprisingly apatite deposits were also identified in the inner medullary collecting ducts and in the thin ascending limbs of the loops of Henle. It was speculated that perhaps the alkali load associated with treatment of cystine stone formers or obstruction of the inner medullary collecting ducts by the cystine plugs resulting in an acidification defect could promote apatite crystallization (Evan et al, 2006b).

(From Evan AP, Lingeman JE, Coe FL, et al. Crystal-associated nephropathy in patients with brushite nephrolithiasis. *Kidney Int* 2005;67:576–91.)

Whether tubular or interstitial calcifications are primarily responsible for renal stone formation is not entirely clear, and it is likely that both mechanisms play a role in particular clinical scenarios. Retention of crystals in the tubular lumen may lead to nephrocalcinosis, which may or may not be associated with renal stone formation. However, these crystals may lead to obstruction-induced tubulopathy and ultimately renal failure. Experimental evidence suggests that crystals bind preferentially to regenerating/redifferentiating renal tubular cells (Verkoelen and Verhulst, 2007). Crystal binding to the surface of these cells is thought to be mediated by a number of luminal membrane molecules, including hyaluronic acid, osteopontin, annexin-II, and nucleolin-related protein. Clinical observation of nephrocalcinosis in 60% of preterm infants may be related to exposure of differentiating renal tubular epithelial cells to crystalluria caused by furosemide treatment (Ezzedeen et al, 1988; Downing et al, 1992). Indeed, the kidneys of these infants have been shown to strongly express hyaluronic acid and osteopontin at the luminal membrane (Verhulst et al, 2005).

Inhibitors and Promoters of Crystal Formation

At the concentrations at which most stone-forming salt components (including calcium, oxalate, and phosphate) are present in urine, urine is supersaturated, thereby favoring crystal formation. However, the presence of molecules that raise the level of supersaturation needed to initiate crystal nucleation or reduce the rate of crystal growth or aggregation prevents stone formation from occurring on a routine basis. Although inhibitors have been identified that prevent calcium oxalate and calcium phosphate crystallization, no specific inhibitors are known that affect uric acid crystallization. Additionally, interference with the site of adhesion of crystals to the renal epithelium can prevent calculus retention and growth (Kumar et al, 2005).

Whole urine, when added to a solution of calcium phosphate, raises the supersaturation level required to initiate calcium phosphate crystallization (formation product) (Fleisch and Bisaz, 1962). Inorganic pyrophosphate was found to be responsible for 25% to 50% of the inhibitory activity of whole urine against calcium phosphate crystallization. Using different methodology, citrate, magnesium, and pyrophosphate together were noted to account for approximately 20% of the inhibitory activity of whole urine, with citrate the most important factor (Bisaz et al, 1978).

Citrate acts as an inhibitor of calcium oxalate and calcium phosphate stone formation by a variety of actions. First, it complexes with calcium, thereby reducing the availability of ionic calcium to interact with oxalate or phosphate (Meyer and Smith, 1975; Pak et al, 1982). Second, it directly inhibits the spontaneous precipitation of calcium oxalate (Nicar et al, 1987) and prevents the agglomeration of calcium oxalate crystals (Kok et al, 1986). Although it has limited inhibitory effect on calcium oxalate crystal growth, it has potent activity in reducing calcium phosphate crystal growth (Meyer and Smith, 1975). Lastly, citrate prevents heterogeneous nucleation of calcium oxalate by monosodium urate (Pak and Peterson, 1986).

The inhibitory activity of magnesium is derived from its complexation with oxalate, which reduces ionic oxalate concentration and calcium oxalate supersaturation (Meyer and Smith, 1975). A recent study showed that magnesium reduced the contact time between calcium and oxalate molecules in vitro, an effect that showed synergism with citrate and was negated by the presence of uric acid (Riley et al, 2013). Pyrophosphate, phosphate, and magnesium have all been shown to inhibit crystal growth, but only high concentrations of magnesium and pyrophosphate have been shown to inhibit aggregation (Kok et al, 1988).

Polyanion macromolecules, including glycosaminoglycans, acid mucopolysaccharides, and RNA, have been shown to inhibit crystal

nucleation and growth by bonding with surface calcium ions. The most prominent glycosaminoglycan in human urine is chondroitin sulfate (Angell and Resnick, 1989). However, among the glycosaminoglycans, heparin sulfate interacts most strongly with calcium oxalate monohydrate crystals (Yamaguchi et al, 1993). Erturk and colleagues (2002) utilized a dye-binding assay to measure urinary glycosaminoglycan concentration and found a significantly lower concentration in stone formers than in controls. Furthermore, recurrent stone formers demonstrated lower levels of glycosaminoglycans than those who had experienced a single stone episode. While these macromolecular proteins have been shown to inhibit stone aggregation, Reid and colleagues (2011) demonstrated through nuclear magnetic resonance spectroscopy that glycosaminoglycans and proteins are strongly integrated into the mineral lattice of apatite-predominant phosphate stones. Furthermore, they found that nonphosphate crystals such as calcium oxalate and uric acid did not exhibit composite lattices containing these proteins. These findings are consistent with plaque formation as apatitic foci that develop in a basement membrane environment rich in extracellular matrix proteins and glycosaminoglycans.

Two urinary glycoproteins, nephrocalcin and Tamm-Horsfall glycoprotein, are potent inhibitors of calcium oxalate monohydrate crystal aggregation (Nakagawa et al, 1987). Nephrocalcin is an acidic glycoprotein containing predominantly acidic amino acids that is synthesized in the proximal renal tubules and the thick ascending limb. In simple solution, nephrocalcin strongly inhibits the growth of calcium oxalate monohydrate crystals (Nakagawa et al, 1987), and it has also been shown to inhibit nucleation and aggregation of calcium oxalate crystals (Coe et al, 1994). Nephrocalcin has been identified in four isoforms: non-stone formers excrete greater quantities of two isoforms associated with the most inhibitory activity, whereas stone formers excrete urine enriched for the two isoforms lacking inhibitory activity (Nakagawa, 1997). The isoforms with inhibitory activity were found to contain γ -carboxyglutamic acid residues that were lacking in the isoforms isolated from stone formers.

Tamm-Horsfall protein is expressed by renal epithelial cells in the thick ascending limb and the distal convoluted tubule as a membrane-anchored protein that is released into the urine after cleavage of the anchoring site by phospholipases or proteases. Tamm-Horsfall is the most abundant protein found in the urine and a potent inhibitor of calcium oxalate monohydrate crystal aggregation, but not growth. The role of Tamm-Horsfall protein in stone formation is controversial and may depend on the state of the molecule itself, which determines whether it functions as an inhibitor or a promoter of crystal formation. In alkaline urine it is a strong inhibitor of calcium oxalate monohydrate crystal aggregation, while in acidic urine it polymerizes into a configuration that promotes crystal aggregation (Hess, 1992). A study using a Tamm-Horsfall knockout (*Thp*^{-/-}) mouse model demonstrated spontaneous formation of calcium oxalate crystals in the kidneys of mice fed ethylene glycol and vitamin D, suggesting a protective role of Tamm-Horsfall protein against crystallization of calcium salts (Mo et al, 2004). A subsequent study on more than 250 Tamm-Horsfall protein-null mice demonstrated a consistent phenotype of progressive renal calcification that consisted of hydroxyapatite in the interstitial space of renal papillae resembling the plaques seen in idiopathic calcium oxalate stone formers (Liu et al, 2010).

Osteopontin, or uropontin, is an acidic phosphorylated glycoprotein expressed in bone matrix and renal epithelial cells of the ascending limb of the loop of Henle and the distal tubule. Osteopontin has been shown to inhibit nucleation, growth, and aggregation of calcium oxalate crystals, as well as to reduce binding of crystals to renal epithelial cells in vitro (Asplin et al, 1998; Wesson et al, 1998). In an osteopontin knockout mouse model, intratubular calcium oxalate crystals could be induced in mice exposed to high levels of oxalate by ethylene glycol feeding (Wesson et al, 2003). Interestingly, in a *Thp*^{-/-} mouse model, mice fed ethylene glycol and vitamin D exhibited a dramatic increase in osteopontin levels over baseline but still formed calcium oxalate crystals (Mo et al, 2004). The authors concluded that osteopontin may

constitute an inducible inhibitor of calcium oxalate crystallization that works in conjunction with constitutively expressed Tamm-Horsfall protein to prevent crystallization.

Urinary prothrombin fragment 1 (F1) is a crystal matrix protein named for its resemblance to the F1 degradation product of prothrombin. Ryall and colleagues (1995) purified urinary prothrombin F1 from human urine and utilized an artificial crystallization system to determine that it was associated with a reduction in crystal aggregation and deposition.

Lastly, inter- α -trypsin is a glycoprotein synthesized in the liver that is composed of three polypeptides (two heavy chains and one light chain), of which bikunin comprises the light chain. Bikunin is a strong inhibitor of calcium oxalate crystallization, aggregation, and growth in vitro (Hochstrasser et al, 1984; Atmani and Khan, 1999), and its expression has been shown to be upregulated in a rat model when exposed to oxalate.

Matrix

Renal calculi consist of both crystalline and noncrystalline components. The noncrystalline component is termed *matrix*, which typically accounts for about 2.5% of the weight of the stone (Boyce and Garvey, 1956). In some cases, matrix comprises the majority of the stone (up to 65%), usually in association with chronic urinary tract infection (Boyce and Garvey, 1956; Allen and Spence, 1966). The exact composition of matrix is difficult to ascertain because only 25% of it is soluble (Ryall, 1993); however, chemical analysis reveals a heterogeneous mixture consisting of approximately 65% protein, 9% nonamino sugars, 5% glucosamine, 10% bound water, and 12% organic ash (Boyce, 1968). Among the proteins incorporated into the matrix substance are Tamm-Horsfall protein, nephrocalcin, a γ -carboxyglutamic acid-rich protein, renal lithostathine, albumin, glycosaminoglycans, free carbohydrates, and a mucoprotein called matrix substance A (Hess and Kok, 1996). Boyce and colleagues (1962) found that substance A is immunologically unique and present in the matrix component of all stone formers. Moore and Gowland (1975) determined that substance A is composed of three or four distinct antigens unique to stones that were detected in the urine of 85% of stone formers but in no normal individuals. A study using reverse-phase, high-performance liquid chromatography and tandem mass spectrometry to evaluate calcium oxalate stones identified 68 distinct proteins with 95% confidence, including a significant number of inflammatory proteins (immunoglobulins, defensin-3, clusterin, complement C3a, kininogen, and fibrinogen) (Canales et al, 2008). Comparing the matrix component of 13 calcium oxalate and 12 calcium phosphate stones, these investigators found that inflammatory proteins comprised the predominant proteins in both stone types, with many proteins in common, suggesting a shared pathogenesis for the two stone types that involves inflammation (Canales et al, 2010). The exact role of matrix in stone formation, whether as promoter, inhibitor, or passive bystander, has yet to be elucidated.

KEY POINTS: PHYSICOCHEMISTRY AND PATHOGENESIS

- Urine must be supersaturated for stones to form.
- Supersaturation alone is not sufficient for crystallization to occur in urine, owing to the presence of urinary inhibitors.
- Nephrocalcin, uropontin, and Tamm-Horsfall protein are important inhibitors of crystal nucleation, growth, or aggregation.
- Urinary calcium and oxalate contribute equally to urinary saturation of calcium oxalate.
- Common calcium stones may originate from subepithelial plaques composed of calcium apatite that serve as an anchor on which calcium oxalate stones can grow.
- The noncrystalline component of stones is matrix, which is composed of a combination of mucoproteins, proteins, carbohydrates, and urinary inhibitors.

MINERAL METABOLISM

Calcium

Thirty to 40 percent of dietary calcium is absorbed from the intestine, with most being absorbed in the small intestine and only approximately 10% absorbed in the colon (Bronner and Pansu, 1999). By a process of intestinal adaptation, absorption of calcium varies with calcium intake. At times of low calcium intake, fractional calcium absorption is enhanced; during high calcium intake, fractional calcium absorption is reduced. With a calcium-rich diet, a nonsaturable, paracellular pathway for calcium absorption predominates. A saturable, vitamin D-dependent transcellular pathway constitutes the major pathway for intestinal calcium absorption when calcium intake is limited; this pathway is downregulated by a diet replete in calcium (Buckley and Bronner, 1980; Bronner et al, 1986). Because of the saturable component of calcium transport, a larger portion of calcium is absorbed when it is divided into several doses taken hours apart than with a large single dose (Phang et al, 1968). A small amount of calcium is secreted into the lumen of the intestine, thereby reducing net calcium absorption such that, overall, 100 to 300 mg of a total average calcium intake of 600 to 1200 mg daily will be absorbed.

Calcium is absorbed in the ionic state, and incomplete calcium absorption is due in part to formation of soluble calcium complexes in the intestinal lumen. **Therefore substances that complex with calcium, such as phosphate, citrate, oxalate, sulfate, and fatty acids, reduce the availability of ionic calcium for absorption (Allen, 1982).** Calcium readily complexes with phosphate in the intestinal lumen, but because calcium phosphate formation is dependent on pH ($pK = 6.1$), high luminal pH favors calcium phosphate complexation, thereby reducing calcium availability. On the other hand, calcium oxalate complex formation displays less pH dependence and complex formation is less reversible. Consequently, an oxalate-rich diet reduces calcium absorption. Transcellular calcium absorption is mediated by $1,25(\text{OH})_2\text{D}_3$ (calcitriol), which is reported to enhance calcium permeability at the brush border of the intestinal epithelial cells (Fontaine et al, 1981).

The active form of vitamin D, $1,25(\text{OH})_2\text{D}_3$, is the most potent stimulator of intestinal calcium absorption. After conversion of 7-dehydrocholesterol in the skin to previtamin D_3 promoted by sunlight, previtamin D_3 is hydroxylated in the liver to 25-hydroxyvitamin D_3 , which is further hydroxylated in the proximal renal tubule to $1,25(\text{OH})_2\text{D}_3$. The conversion of 25-hydroxyvitamin D_3 to $1,25(\text{OH})_2\text{D}_3$ is stimulated by parathyroid hormone (PTH) and by hypophosphatemia. **A decrease in serum calcium increases secretion of PTH, which in turn directly stimulates the enzyme 1α -hydroxylase, which is located in the mitochondria of the proximal renal tubule.** After transport via the bloodstream to the intestine, $1,25(\text{OH})_2\text{D}_3$ binds to the vitamin D receptor in the brush border membrane epithelial cells to enhance calcium absorption.

Calcitriol acts on the bone and kidney in addition to its action in increasing intestinal calcium absorption. In the bone, $1,25(\text{OH})_2\text{D}_3$, along with PTH, promotes the recruitment and differentiation of osteoclasts that subsequently mobilize calcium from the bone. Consequently, the filtered load of calcium and phosphate increases. However, PTH increases renal calcium reabsorption and enhances phosphate excretion, leading to a further net increase in serum calcium, which suppresses further PTH secretion and synthesis of $1,25(\text{OH})_2\text{D}_3$. Calcitriol modulates parathyroid function by inhibiting synthesis of PTH through enhanced vitamin D receptor and calcium-sensing receptor (CaSR) expression in the parathyroid glands (Dusso et al, 2005).

PTH is critical in maintaining normal calcium concentration in the extracellular fluid. PTH is an 84-amino acid protein that is the cleavage product of the precursor protein prepro-PTH. **Only mature PTH is secreted from the parathyroid gland, and the most potent stimulus for its secretion is a decrease in serum calcium (Sherwood et al, 1968).** In response to serum calcium levels, the G-protein-coupled extracellular CaSR regulates PTH secretion and

renal tubular calcium reabsorption (Devuyst and Pirson, 2007). PTH stimulates mobilization of calcium from bone through the action of osteoclasts, further raising serum calcium and phosphorus. The action of PTH is mediated through changes in cyclic adenosine monophosphate and phospholipase C (Dunlay and Hruska, 1990; Muff et al, 1992). **At the kidney, PTH enhances renal calcium reabsorption and reduces renal tubular reabsorption of phosphate.** It also stimulates synthesis of $1,25(\text{OH})_2\text{D}_3$, which leads to enhanced intestinal calcium and phosphate absorption. PTH has no direct effect on intestinal calcium absorption.

Calcium absorption in the kidney is complex, but recent work has begun to elucidate the proteins and mechanisms involved. On average, only 1% to 3% of filtered calcium is excreted in the urine, with most being reabsorbed paracellularly in the renal proximal tubule (60% to 65%) and thick ascending limb of the loop of Henle (25% to 30%). The remaining 8% to 10% of filtered calcium is reabsorbed transcellularly in the distal convoluted tubule (Friedman, 2007).

The paracellular absorption of calcium in the proximal tubule and thick ascending limb of the loop of Henle occurs by several mechanisms. First, calcium travels through paracellular channels found at the tight junctions of epithelial cells in the proximal tubule. The integral membrane proteins of the tight junction include occludin, junctional adhesion molecules, and claudins (Furuse et al, 1993; Ebnet et al, 2004; Hou, 2013). Claudins are a family of proteins with four transmembrane domains (Lal-Nag and Morin, 2009; Hou, 2013), including claudin-2, which has been implicated in paracellular reabsorption of calcium and other cations in the proximal tubule (Muto et al, 2010), and claudin-16 and claudin-19, which form a paracellular channel complex that allows selective cation permeation in the thick ascending limb (Hou et al, 2008, 2009).

Calcium is passively reabsorbed from the lumen of the thick ascending limb of the loop of Henle into the interstitial space through a paracellular pathway driven by a lumen-positive transepithelial voltage gradient (Hou, 2013). The positive luminal voltage occurs as a result of apical potassium secretion and basolateral chloride secretion, as well as by way of a transepithelial NaCl concentration gradient over the cation-selective paracellular channel in the thick ascending limb.

The CaSR plays a role in renal handling of calcium, and its expression predominates in the thick ascending limb. Serum calcium stimulates the CaSR to increase expression of claudin-14, which blocks the calcium channels formed by the claudin-16/19 complex, thereby reducing paracellular calcium reabsorption (Gong et al, 2012; Toka et al, 2012).

Transcellular calcium absorption in the distal convoluted tubule occurs via several mechanisms (Mensenkamp et al, 2006, 2007). Calcium enters the epithelial cells of the distal tubule through a transcellular channel (transient receptor potential vanilloid 5, or TRPV5), which is unique among other channels in the TRP family because of its high calcium selectivity. Calcium flux through TRPV5 into the distal tubule cells is controlled at several levels, including TRPV5 gene expression, feedback inhibition, and trafficking across the plasma membrane. Inactivation of TRPV5 in mice leads to severe hypercalciuria, which is compensated for by increased intestinal calcium absorption resulting from enhanced calcitriol synthesis. Calcium is bound in the cell to a chaperone protein (calbindin-D28k), which facilitates diffusion across the cell from the apical to the basolateral space where calcium can then exit.

Phosphorus

Like calcium, inorganic phosphate absorption is dependent on both saturable transcellular and nonsaturable paracellular transport. At low phosphorus concentrations (1 to 3 mmol/L), saturable absorptive transport occurs. At higher phosphorus levels, absorption increases without saturation (Walton and Gray, 1979). Approximately 60% of dietary phosphate is absorbed in the intestine. Active absorption of phosphate from the intestine involves a $1,25(\text{OH})_2\text{D}_3$ -regulated, sodium-dependent transport process (Danisi and Straub,

1980; Lee et al, 1986). Phosphate absorption is highly pH dependent; low luminal pH reduces while high pH enhances phosphate transport.

Approximately 65% of absorbed phosphate is excreted by the kidney and the remainder by the intestine. In normal healthy adults, 80% to 90% of the filtered load of phosphate is reabsorbed in the renal tubule and 10% to 20% is excreted in the urine. **Regulation of renal phosphate handling is primarily by way of PTH, which inhibits renal tubular reabsorption of filtered phosphate.**

Magnesium

Magnesium is absorbed from the intestine by passive diffusion or active transport, although passive diffusion accounts for most of the net magnesium absorption. Magnesium is absorbed in both the large and small intestine, with the majority absorbed from the distal small intestine. Hormonal regulation of magnesium is primarily through vitamin D.

Oxalate

Oxalate metabolism differs markedly from calcium metabolism. Although 30% to 40% of ingested calcium is absorbed from the intestine, only 6% to 14% of ingested oxalate is absorbed (Holmes et al, 1995; Hesse et al, 1999). Oxalate absorption occurs throughout the intestinal tract, with about half or more occurring in the small intestine and half in the colon (Holmes et al, 1995). Although oxalate absorption is difficult to measure directly, it has historically been estimated by urinary oxalate excretion, a relationship that is valid only if there is a linear relationship between ingested and excreted oxalate and if absorbed oxalate is not significantly taken up in the tissues, metabolized, or secreted back into the intestine. Holmes and colleagues (2001) in fact demonstrated that the relationship between ingested oxalate and absorbed oxalate is curvilinear, owing to higher absorption of oxalate at low intake than at high intake. Moreover, they showed that oxalate absorption varies widely among individuals, ranging from 10% to 72% of ingested oxalate. A recent study suggested that hyperoxaluric stone formers absorb more oxalate in response to an oral oxalate load than stone formers with normal oxalate excretion (Krishnamurthy et al, 2003). Knight and colleagues (2007), however, found no difference between normal subjects and stone formers in intestinal absorption or renal handling of oxalate. In patients with small bowel disease or history of intestinal resection and an intact colon, oxalate absorption is markedly increased (Barilla et al, 1978).

Oxalate transport occurs via both transcellular and paracellular pathways. Although transport by way of paracellular pathways and some nonmediated transcellular pathways is primarily passive, driven by electrochemical or concentration gradients, transcellular transport is largely actively mediated by membrane carriers. The transport protein responsible for oxalate secretion has been suspected to belong to the SLC26 family of solute-linked carrier (SLC) anion exchangers. A putative anion exchange transporter, SLC26A6, that is expressed in the apical membrane of small intestinal and perhaps colonic epithelial cells has been implicated in intestinal oxalate transport (Hatch and Freel, 2005). Evidence suggests that oxalate may be secreted, as well as absorbed, in the intestine (Jiang et al, 2006). In vitro flux studies using intestinal segments of mutant mice lacking SLC26A6 showed enhanced net absorption of oxalate as a result of defective oxalate secretion. Furthermore, in vivo *Slc26a6*-null mice were found to have elevated plasma and urinary oxalate levels, reduced fecal oxalate excretion, and a high incidence of calcium oxalate bladder stones compared with wild-type mice. These findings provide compelling evidence for a possible role of SLC26A6 in oxalate secretion and suggest a potential target for therapeutic agents that modify urinary oxalate absorption.

A number of other factors can influence oxalate absorption, including the presence of oxalate-binding cations such as calcium or magnesium and oxalate-degrading bacteria. Coingestion of calcium- and oxalate-containing foods leads to formation of calcium oxalate complexes, which limits the availability of free

oxalate ion for absorption (Liebman and Chai, 1997; Hess et al, 1998; Penniston and Nakada, 2009). Oxalate-degrading bacteria, notably *Oxalobacter formigenes*, use oxalate as an energy source and consequently reduce intestinal oxalate absorption. The mechanism of action of *O. formigenes* in reducing urinary oxalate excretion may not be entirely accounted for by degradation of intestinal oxalate. In vivo and ex vivo studies in *O. formigenes*-colonized rats demonstrated reduced urinary oxalate excretion and net colonic oxalate secretion, suggesting that *O. formigenes* may interact directly with intestinal mucosal cells to stimulate secretion of endogenously derived oxalate (Hatch et al, 2006).

The potential for therapeutic use of probiotics or oxalate-degrading enzyme preparations has been explored in mice models and in several short-term clinical trials. In two knockout mice models, one of which resembles primary hyperoxaluria, administration of an oxalate-degrading enzyme reduced urinary oxalate and prevented nephrocalcinosis (Grujic et al, 2009). Likewise, in a small study of patients with primary hyperoxaluria and normal renal function or varying degrees of renal failure, administration of *O. formigenes* was associated with a reduction in serum and/or urinary oxalate (Hoppe et al, 2006). However, a subsequent randomized trial in 43 patients with primary hyperoxaluria administered oral *O. formigenes* versus placebo failed to show a treatment effect in reducing urinary oxalate (Hoppe et al, 2011). Similarly, although one uncontrolled study (Campieri et al, 2001) of calcium oxalate stone formers with mild hyperoxaluria showed a 24% to 40% reduction in urinary oxalate with the administration of a preparation of mixed lactic acid bacterium species, a randomized, controlled trial (Goldfarb et al, 2007) failed to demonstrate an effect of the same probiotic. At this time, the contribution of *O. formigenes* to the overall risk of stone formation is not fully understood.

Absorbed oxalate is nearly completely excreted in the urine (Hodgkinson and Wilkinson, 1974; Prenan et al, 1982). Urinary oxalate is derived from both endogenous production in the liver (from ascorbic acid and glycine) and dietary sources. Recent evidence suggests that, on average, half of urinary oxalate is derived from the diet, with the precise amount depending on the relative amount of ingested calcium and oxalate (Holmes et al, 2001).

It is estimated that between 86% and 98% of oxalate is ultrafilterable. However, renal tubular handling of oxalate has not been clearly defined, although both secretion and reabsorption have been suspected. There is evidence from a number of animal models of a secretory pathway for oxalate that likely resides in the renal proximal tubule (Holmes and Assimos, 2004). The SLC26 transport proteins responsible for oxalate secretion include one implicated in intestinal oxalate secretion, SLC26A6. However, to date, no specific transporter has been definitively linked to renal oxalate secretion, and a recent study in a rat model investigating the role of a likely candidate, the basolateral anion exchanger sulfate anion transporter-1 (SAT1, or SLC26A1), found no correlation between changes in renal expression of SAT1 messenger RNA or protein and hyperoxaluria (Freel and Hatch, 2012).

Clinical evidence also supports renal oxalate secretion, although it is not clear if renal handling of oxalate differs between stone formers and non-stone formers (Schwille et al, 1989; Holmes et al, 2005; Knight et al, 2007). Holmes and coworkers (2005) studied six normal subjects administered increasing oral oxalate loads and found oxalate clearance ratios consistent with renal oxalate secretion, with up to 50% of urinary oxalate accounted for by oxalate secretion at the highest oxalate load. These investigators subsequently compared plasma and urine oxalate levels in idiopathic hypercalciuric stone formers versus normal subjects both while fasting and after consuming three low-oxalate meals (Bergsland et al, 2011). Despite no difference in plasma oxalate between the two groups in either the fasting or fed states, urinary oxalate and fractional excretion was higher in patients than normal subjects. Of note, fractional excretion of oxalate exceeded 1, indicating oxalate secretion, in almost a third of patients and no controls, suggesting that renal oxalate secretion may play a role in regulating plasma oxalate levels.

KEY POINTS: MINERAL METABOLISM

- Calcium absorption occurs primarily in the small intestine at a rate that is dependent on calcium intake.
- 1,25-Dihydroxyvitamin D₃ is the most potent stimulator of intestinal calcium absorption.
- PTH stimulates 1 α -hydroxylase in the proximal tubule of the kidney to convert 25-hydroxyvitamin D₃ to 1,25(OH)₂D₃.
- PTH enhances proximal tubular reabsorption of calcium and renal phosphate excretion.
- Intestinal oxalate absorption is influenced by luminal calcium, magnesium, and oxalate-degrading bacteria.

PATHOPHYSIOLOGY OF UPPER URINARY TRACT CALCULI

Classification of Nephrolithiasis

The most common component of urinary calculi is calcium, which is a major constituent of nearly 80% of stones. Calcium oxalate comprises about 60% of all stones; mixed calcium oxalate and hydroxyapatite make up 20% and brushite stones make up 2%. Uric acid and struvite (magnesium ammonium phosphate) each comprise approximately 7% of stones, and cystine stones represent only about 1% (Table 51-1) (Wilson, 1989). Stones associated with medications and their byproducts, such as triamterene, silica, indinavir, and ephedrine, are uncommon and usually preventable.

Most classification systems for nephrolithiasis differentiate stones on the basis of the underlying metabolic or environmental abnormalities with which they are associated (Table 51-2). A number of pathophysiologic derangements contribute to calcium stone formation, either alone or in combination, including hypercalciuria, hypocitraturia, hyperuricosuria, and hyperoxaluria (Coe et al, 2005). Uric acid, cystine, and struvite stones form in relatively unique settings; uric acid stones form only in an acid urine, cystine stones are the result of impaired renal reabsorption of cystine, and infection stones occur in alkaline urine produced by urease-producing bacteria. For some stones such as cystine, knowledge of the chemical composition of the stone may provide sufficient infor-

mation to initiate appropriate therapy. However, because of the multiple causes associated with calcium-based stones, an understanding of the underlying metabolic disorders and environmental factors that predispose to stone formation is required in order to implement a rational treatment plan. Recent investigation into the molecular and genetic causes of stone formation may ultimately translate into newer treatment strategies (Frick and Bushinsky, 2003; Langman, 2004; Devuyst and Pirson, 2007).

Calcium Stones

Hypercalciuria

Hypercalciuria is the most common abnormality identified in calcium stone formers (Pak et al, 1982; Coe et al, 1992; Bushinsky,

TABLE 51-1 Stone Composition and Relative Occurrence

STONE COMPOSITION	OCCURRENCE (%)
CALCIUM-CONTAINING STONES	
Calcium oxalate	60
Hydroxyapatite	20
Brushite	2
NON-CALCIUM-CONTAINING STONES	
Uric acid	7
Struvite	7
Cystine	1-3
Triamterene	<1
Silica	<1
2,8-Dihydroxyadenine	<1

TABLE 51-2 Diagnostic Classification of Nephrolithiasis

CONDITION	METABOLIC/ENVIRONMENTAL DEFECT	PREVALENCE (%)
Absorptive hypercalciuria	Increased gastrointestinal calcium absorption	20-40
Renal phosphate leak	Impaired renal phosphorus absorption	
Renal hypercalciuria	Impaired renal calcium reabsorption	5-8
Resorptive hypercalciuria	Primary hyperparathyroidism	3-5
Hyperuricosuric calcium nephrolithiasis	Dietary purine excess, uric acid overproduction	10-40
Hypocitraturic calcium nephrolithiasis		10-50
Isolated	Idiopathic	
Chronic diarrheal syndrome	Gastrointestinal alkali loss	
Distal renal tubular acidosis	Impaired renal acid excretion	
Thiazide-induced	Hypokalemia	
Hyperoxaluric calcium nephrolithiasis		2-15
Primary hyperoxaluria	Oxalate overproduction	
Dietary hyperoxaluria	Increased dietary oxalate	
Enteric hyperoxaluria	Increased intestinal oxalate absorption	
Hypomagnesiuric calcium nephrolithiasis	Decreased intestinal magnesium absorption	5-10
Gouty diathesis	Low urinary pH	15-30
Cystinuria	Impaired renal cystine reabsorption	<1
Infection stones	Infection with urease-producing bacteria	1-5
Low urine volume	Inadequate fluid intake	10-50
Miscellaneous or no abnormality	NA	<3

Modified from Pearle MS, Pak CY. Renal calculi: a practical approach to medical evaluation and management. In: Andreucci VE, Fine LG, editors. International yearbook of nephrology. New York: Oxford University Press; 1996. p. 69–80.

1998). However, the role of hypercalciuria in stone formation is controversial, because of the overlap in urine calcium levels between stone formers and non-stone formers (Robertson and Morgan, 1972; Coe et al, 1992). There are several lines of evidence that support a pathogenetic role for hypercalciuria in stone formation. First, hypercalciuria is common in stone-forming patients, occurring in 35% to 65% of patients (Levy et al, 1995). Indeed, treatment strategies aimed at reducing urinary calcium levels are associated with a reduction in stone recurrence rates (Pearle et al, 1999), and medical therapy often fails in patients with persistent hypercalciuria (Strauss et al, 1982). In addition, multivariate analysis of a subset of men and women from three large epidemiologic studies in whom 24-hour urine studies were available revealed that, after adjusting for other factors, the risk of incident stone formation increased with increasing urinary calcium (Curhan et al, 2001). Lastly, recent investigations of Randall plaques as potential precursors to calcium stone formation have shown that plaques occur more commonly in stone formers and their number directly correlates with urine calcium levels and number of stone episodes (Kuo et al, 2003b; Kim et al, 2005).

High urinary calcium concentrations lead to increased urinary saturation of calcium salts (Pak and Holt, 1976) and reduced urinary inhibitory activity by way of complexation with negatively charged inhibitors such as citrate and chondroitin sulfate (Zerwekh et al, 1988). The normal kidney filters approximately 270 mmol of calcium daily and reabsorbs all but 4 mmol (Bushinsky, 1998). However, a variety of conditions lead to elevated urinary calcium levels and increased urinary saturation of calcium salts. Criteria defining hypercalciuria are variable, but the strictest definition classifies hypercalciuria as greater than 200 mg of urinary calcium/day after adherence to a 400-mg calcium, 100-mg sodium diet for 1 week (Menon, 1986). Parks and Coe (1986) defined hypercalciuria as excretion of greater than 4 mg/kg/day or greater than 7 mmol/day in men and 6 mmol/day in women. However, arguably a threshold level of calcium that separates hypercalciuria from normocalciuria is artificial, and urinary calcium demonstrates a spectrum of effects over its range by which higher or lower calcium levels are associated with a greater or lesser effect.

Historically, the term *idiopathic hypercalciuria* was applied to stone formers for whom classification of their metabolic abnormality was difficult. Calcium transport is regulated at three sites: intestine, bone, and kidney. Dysregulation at any of these sites can lead to hypercalciuria. In 1974, Pak and colleagues divided hypercalciuria into three distinct subtypes on the basis of unique pathophysiologic abnormalities: absorptive hypercalciuria due to increased intestinal absorption of calcium, renal hypercalciuria due to primary renal leak of calcium, and resorptive hypercalciuria due to increased bone demineralization.

Although historically this classification system has been used because of its utility in simplifying the understanding and treatment of specific metabolic derangements, many have argued that hypercalciuria is associated with multiple, interrelated disturbances that cannot be readily separated into a specific organ system (Coe et al, 1992). Furthermore, studies into the molecular mechanisms of stone formation have identified gene mutations that can affect several organ systems, culminating in hypercalciuria (Frick and Bushinsky, 2003; Langman, 2004). Indeed, utilization of a classification system for hypercalciuria has not been associated with superior therapeutic efficacy and is therefore not routinely implemented in clinical practice. Although improved understanding of the molecular and genetic causes of stone disease may well change the categorization and management of stones in the future, for the purposes of this chapter, the standard classification system will be utilized.

Absorptive Hypercalciuria. Absorptive hypercalciuria (AH) is defined as increased urinary calcium excretion (>0.2 mg/mg creatinine) after an oral calcium load. Although fasting urinary calcium is usually normal in AH (<0.11 mg/dL glomerular filtration), severe forms of AH may occasionally be associated with fasting hypercalciuria as well. The underlying pathophysiologic abnormality in AH is increased intestinal absorption of calcium, which occurs in

approximately 30% of stone formers. Dietary calcium restriction may normalize urinary calcium in some patients with AH (type II) but not in others (type I). The added systemic load of calcium caused by intestinal calcium hyperabsorption results in a transient increase in serum calcium, which suppresses serum PTH and results in increased renal filtration of calcium, ultimately leading to hypercalciuria. Because the increase in intestinal absorption of calcium is matched by enhanced renal calcium excretion, serum calcium level remains normal.

The cause of increased intestinal absorption of calcium has been variously ascribed to vitamin D-independent and dependent processes, as well as to upregulation of the vitamin D receptor (Breslau et al, 1992). However, no proposed mechanism completely accounts for all the findings associated with absorptive hypercalciuria, and there is no clear evidence that upregulation of intestinal calcium absorption is the primary cause. There are several genetic abnormalities that can potentially impact vitamin D activity. The active form of vitamin D, $1,25(\text{OH})_2\text{D}_3$, is generated by way of 1-hydroxylation of $25(\text{OH})\text{D}_3$ by the gene product of cytochrome P450 (CYP) 27B1 (CYP27B1), which is present in a variety of tissues. The mitochondrial enzyme $1,25(\text{OH})_2\text{D}$ -24-hydroxylase (CYP24A1), which is present in the intestine and kidney, inactivates both major vitamin D metabolites, $25(\text{OH})\text{D}_3$ and $1,25(\text{OH})_2\text{D}_3$. Bi-allelic mutations in CYP24A1 have been shown to reduce activity of the enzyme, resulting in elevated levels of $1,25(\text{OH})_2\text{D}_3$, particularly in individuals taking large amounts of vitamin D (Schlingmann et al, 2011). Mutations in this gene are responsible for increased sensitivity to vitamin D supplementation in the autosomal recessive disorder idiopathic infantile hyperkalemia. In adults, recessive mutations in CYP24A1 have been associated with a syndrome characterized by hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis (Dinour et al, 2013; Nesterova et al, 2013). Genome-wide association studies revealed an association between CYP24A1 variants and serum vitamin D concentrations (Wang et al, 2010). The frequency of $1,25(\text{OH})_2\text{D}$ -24-hydroxylase deficiency is estimated at 4% to 20% in the general population (Nesterova et al, 2013). However, while these mutations may be common, not all affected individuals will demonstrate clinically significant abnormalities.

Hypersensitivity to vitamin D has also been shown to increase intestinal calcium absorption and cause hypercalciuria (Bushinsky and Monk, 1998). Moreover, several studies have linked hypercalciuria and the vitamin D receptor (VDR) gene. Jackman and colleagues (1999) identified a polymorphism in VDR in 19 patients with a family history of nephrolithiasis and hypercalciuria, thereby establishing a potential link. Likewise, Scott and colleagues (1999) identified linkage between a microsatellite marker and the VDR locus on chromosome 12q12-q14 in a cohort of 47 French-Canadian pedigrees with idiopathic hypercalciuria and calcium nephrolithiasis.

Other studies, however, failed to confirm the association of VDR abnormalities with hypercalciuria (Zerwekh et al, 1995, 1998). Indeed, other genetic loci have been identified in association with AH. Reed and colleagues (1999, 2002) mapped the locus for an inherited form of AH to chromosome 1q23.3-q24 and found a putative gene (subsequently shown by others to be homologous with the rat soluble adenylate cyclase gene) in this region in 12 unrelated white AH patients.

Another proposed etiology of AH is renal phosphate wasting leading to a subsequent increase in active vitamin D. Patients with hereditary hypophosphatemic rickets with hypercalciuria (HHRH) manifest this abnormality, which is characterized by decreased renal reabsorption of phosphate, hypophosphatemia, and a subsequent compensatory increase in vitamin D levels, leading to enhanced absorption of calcium and phosphate from the intestine and hypercalciuria (Tieder et al, 1987). The mutations associated with HHRH are thought to be inherited in an autosomal recessive pattern. Candidate genes for HHRH include *SLC34A1* and *SLC34A3*, which encode sodium-coupled phosphate transporters located in the apical membrane of the renal proximal tubule (NaPi-IIa and NaPi-IIc, respectively) (Devuyst and Pirson, 2007). Renal phosphate leak,

however, is a rare cause of nephrolithiasis, affecting at most 2% to 4% of patients (Levy et al, 1995).

Renal Hypercalciuria. The kidney filters approximately 270 mmol of calcium and must reabsorb more than 98% of it to maintain calcium homeostasis (Bushinsky, 1998). Approximately 70% of calcium reabsorption occurs in the proximal tubule, with paracellular pathways predominating (Frick and Bushinsky, 2003). In renal hypercalciuria, impaired renal tubular reabsorption of calcium results in elevated urinary calcium levels leading to secondary hyperparathyroidism (Coe et al, 1973). Serum calcium levels remain normal because the renal loss of calcium is compensated by enhanced intestinal absorption of calcium and bone resorption as a result of increased secretion of PTH and enhanced synthesis of $1,25(\text{OH})_2\text{D}_3$. **High fasting urinary calcium levels (>0.11 mg/dL glomerular filtration) with normal serum calcium values are characteristic of renal hypercalciuria.** The elevated fasting urinary calcium and serum PTH levels differentiate renal from absorptive hypercalciuria.

The actual cause of renal calcium leak is not known. However, insight into the abnormalities associated with renal hypercalciuria comes from studies of several monogenetic disorders associated with hypercalciuria and nephrolithiasis (Gambero et al, 2004; Langman, 2004; Devuyt and Pirson, 2007; Ferraro et al, 2013a). Dent disease (X-linked recessive nephrolithiasis) is linked to defects in chloride channel-5 (ClC-5), which is located in the proximal renal tubule, the thick ascending limb of the loop of Henle, and the α -type intercalated cells of the collecting ducts. Dent disease is characterized by hypercalciuria, proteinuria, nephrolithiasis, nephrocalcinosis, and progressive renal failure. Although the exact mechanism by which loss of ClC-5 results in hypercalciuria is not well understood, it may involve loss of PTH as part of the low-molecular-weight proteinuria, leading to elevated calcitriol levels (Reinhart et al, 1995; Nakazato et al, 1997).

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is caused by mutations in claudin-16 (also known as paracellin-1) and claudin-19, members of the claudin gene family of tight junction proteins that are involved in the voltage-driven paracellular reabsorption of magnesium and calcium in the thick ascending limb and distal convoluted tubule (Simon et al, 1999; Konrad et al, 2006). FHHNC patients develop a characteristic triad of hypomagnesemia, hypercalciuria, and nephrocalcinosis as a result of progressive magnesium and calcium wasting. Other claudin abnormalities have also been associated with nephrolithiasis. A genome-wide association study conducted in 3773 hypercalciuric kidney stone patients and 42,510 control subjects from Iceland and the Netherlands identified four common, synonymous variants in the claudin-14 gene locus that were found to be significantly associated with kidney stones and reduced bone mineral density (Thorleifsson et al, 2009). Claudin-14 deregulation blocks the claudin-16 channel and phenocopies FHHNC to a variable degree.

Bartter syndrome encompasses a group of autosomal recessive disorders involving dysfunction in the thick ascending limb of the loop of Henle that is characterized by salt wasting and hypokalemic metabolic acidosis, with variable occurrence of hypercalciuria and nephrolithiasis (Devuyt and Pirson, 2007). This disorder arises from a mutation in any of the genes encoding membrane proteins involved in transepithelial sodium chloride transport across the thick limb of the loop of Henle: *SLC12A1*, which encodes the $\text{Na}^+, \text{K}^+, 2\text{Cl}^-$ cotransporter, NKCC2; *KCNJ*, which encodes the apical renal outer medullary potassium channel, ROMK; *CLCNKB*, which encodes the basolateral chloride channel, ClC-Kb; and *BSND*, which encodes a subunit (Barttin) for the chloride channel proteins ClC-Ka and ClC-Kb.

Activating mutations in the gene encoding the CaSR have been associated with an autosomal dominant form of hypocalcemia by which low serum PTH levels lead to reduced renal calcium reabsorption and subsequent hypocalcemia and hypercalciuria (Devuyt and Pirson, 2007). A potent activating mutation in the CaSR has been associated with salt-losing nephropathy and secondary hyperaldosteronism (Bartter syndrome type V), which is likely related to

dysfunction of ROMK as a result of constitutive activation of the abnormal CaSR (Vargas-Poussou et al, 2002). The CaSR regulates calcium reabsorption in the thick ascending limb through changes in paracellular permeability (Loupy et al, 2012).

Loss-of-function polymorphisms in the CaSR gene have also been associated with idiopathic nephrolithiasis. Two synonymous single nucleotide polymorphisms (rs6776158 and rs1501899) that significantly reduce renal CaSR messenger RNA levels have been shown to be highly associated with normocitraturic nephrolithiasis (Vezzoli et al, 2010, 2011). Reduced CaSR expression can increase paracellular calcium reabsorption in the thick ascending limb of the loop of Henle, leading to interstitial calcium precipitation and hypocalciuria. Diminished calcium delivery to the collecting duct may impact the cellular mechanism for urinary acidification and concentration, leading to calcium oxalate stone formation. Other mutations in the genes for the $\text{Na}^+, \text{K}^+, 2\text{Cl}^-$ cotransporter NKCC2 and the potassium channel ROMK have been associated with autosomal recessive disorders characterized by fasting hypercalciuria and nephrocalcinosis.

Understanding these genetic disorders has the potential to further elucidate the tubular handling of calcium and the pathophysiology of renal hypercalciuria.

Resorptive Hypercalciuria. Resorptive hypercalciuria is an infrequent abnormality most commonly associated with primary hyperparathyroidism. Primary hyperparathyroidism is the cause of nephrolithiasis in about 5% of cases (Broadus, 1989). Excessive PTH secretion from a parathyroid adenoma leads to excessive bone resorption and increased renal synthesis of $1,25(\text{OH})_2\text{D}_3$, which in turn enhances intestinal absorption of calcium. The net effect is elevated serum and urine calcium levels and reduced serum phosphorus levels. Although most patients with primary hyperparathyroidism demonstrate hypercalcemia and hypercalciuria, a normal serum calcium level in the presence of an inappropriately high serum PTH value may be seen in some cases, making the diagnosis more difficult. Administration of a thiazide diuretic will enhance renal calcium reabsorption and exacerbate the hypercalcemia, thereby facilitating the diagnosis ("thiazide challenge") (Eisner et al, 2009).

Primary hyperparathyroidism is associated with nephrolithiasis in less than 5% of affected individuals (Heath et al, 1980; Parks et al, 1980). However, the diagnosis should be suspected in patients with nephrolithiasis and serum calcium levels greater than 10.1 mg/dL (Broadus et al, 1980; Menon, 1986). Serum calcium levels can vary by up to 5%, and patients with mild hyperparathyroidism may exhibit relatively small increases of serum calcium (Yendt and Gagne, 1968). Therefore repeated measurements of serum calcium, along with serum intact PTH, may be necessary to make the diagnosis. Measurement of serum ionized calcium may help in equivocal cases because ionized calcium may be elevated in the setting of normal serum calcium (Yendt and Gagne, 1968). PTH also increases excretion of bicarbonate and phosphorus from the proximal renal tubule, resulting in phosphaturia and mild hyperchloremic acidosis.

Sarcoid and Granulomatous Disease. Additional, rare causes of resorptive hypercalciuria include hypercalcemia of malignancy, sarcoidosis, thyrotoxicosis, and vitamin D toxicity. Many granulomatous diseases, including tuberculosis, sarcoidosis, histoplasmosis, leprosy, and silicosis, have been reported to produce hypercalcemia. Among these, sarcoidosis is most commonly associated with urolithiasis. The hypercalcemia in sarcoidosis is due to the production of $1,25(\text{OH})_2\text{D}_3$ from 1α -hydroxylase present in macrophages of the sarcoid granuloma, causing increased intestinal absorption of calcium, hypercalcemia, and hypercalciuria (Hendrix, 1966; Bell et al, 1979). Pulmonary alveolar cells and lymph node homogenates in patients with sarcoidosis are capable of synthesizing vitamin D, a function usually limited to the kidney. Most patients with sarcoidosis have a suppressed level of PTH secondary to hypercalcemia (Cushard et al, 1972). Sarcoidosis can also be differentiated from other diagnoses by the rapid resolution of hypercalcemia with initiation of corticosteroid therapy (Breslau et al, 1982).

Malignancy-Associated Hypercalcemia. While primary hyperparathyroidism is the most common cause of hypercalcemia in an outpatient setting, malignancy is the main cause of hypercalcemia in hospitalized patients (Rizzoli and Bonjour, 1992). An assay for intact PTH can help distinguish patients with hyperparathyroidism from those with other causes of hypercalcemia (Burtis et al, 1990). Tumors in patients with humoral hypercalcemia produce a PTH-related protein (PTHrP) whose production is regulated by CaSRs on the cell surface (Chattopadhyay, 2006). Lung and breast cancers account for about 60% of malignancy-associated hypercalcemia, whereas renal cell (10% to 15%), head and neck (10%), and hematologic cancers such as lymphoma and myeloma (10%) account for the rest. Although direct mechanical destruction of bone constitutes one cause of hypercalcemia, many tumors secrete humoral factors, including PTHrP, transforming growth factor- α , and cytokines such as interleukin-1 and tumor necrosis factor, which activate osteoclasts and result in bone lysis and hypercalcemia (Burtis et al, 1990; Mundy, 1990; Edelson and Kleerekoper, 1995).

Glucocorticoid-Induced Hypercalcemia. Glucocorticoids can significantly alter calcium metabolism through their actions on bone, intestine, and parathyroid glands. Their most potent effect is related to calcium metabolism in bones, where glucocorticoids promote bone resorption and reduce bone formation, ultimately leading to osteopenia with chronic use (Manelli and Giustina, 2000). Additionally, they stimulate release of PTH (Fucik et al, 1975). On the other hand, glucocorticoids inhibit intestinal absorption of calcium, which accounts for their effectiveness in preventing hypercalciuria induced by sarcoidosis (Manelli and Giustina, 2000). The net effect probably favors promotion of stone formation because nephrolithiasis is common in patients with Cushing syndrome (Faggiano et al, 2003). In one study, stones were found in 50% of patients with active Cushing syndrome, 27% of cured patients, and 6.5% of controls. Compared to controls, patients with active disease had a significantly higher prevalence of hypercalciuria, hypocitraturia, and hyperuricosuria, but these patients were also at greater risk of obesity and diabetes, which have been linked to stone formation (Faggiano et al, 2003).

Hyperoxaluria

Hyperoxaluria, defined as urinary oxalate greater than 40 mg/day, leads to increased urinary saturation of calcium oxalate and subsequent promotion of calcium oxalate stones. Additionally, oxalate

has been implicated in crystal growth and retention by means of renal tubular cell injury mediated by lipid peroxidation and the generation of oxygen free radicals (Ravichandran and Selvam, 1990). Membrane injury facilitates the fixation of calcium oxalate crystals and subsequent crystal growth. Antioxidant therapy has been shown to prevent calcium oxalate precipitation in the rat kidney and to reduce oxalate excretion in stone patients (Selvam, 2002). Similarly, calcium oxalate crystal deposition on urothelium in vitro was prevented by free radical scavengers such as phytic acid and mannitol, purportedly by protecting the membrane from free radical-mediated damage (Thamilselvan and Selvam, 1997; Selvam, 2002). Recent human studies, however, failed to demonstrate increases in markers of oxidative stress or renal injury in normal subjects and stone formers ingesting large doses of oxalate (up to 8 mmol), thus calling into question the importance of oxalate-induced cell membrane damage in calcium oxalate stone formation (Knight et al, 2007).

Causes of hyperoxaluria include disorders in biosynthetic pathways (primary hyperoxaluria); intestinal malabsorptive states associated with inflammatory bowel disease, celiac sprue, or intestinal resection (enteric hyperoxaluria); and excessive dietary intake or high substrate levels (vitamin C) (dietary hyperoxaluria).

Primary Hyperoxaluria. The primary hyperoxalurias (PHs) are the result of rare autosomal recessive inherited disorders in glyoxylate metabolism by which the normal conversion of glyoxylate to glycine is prevented, leading to preferential oxidative conversion of glyoxylate to oxalate, an end product of metabolism (Fig. 51-6). The markedly high levels of urinary oxalate that ensue (>100 mg/day) lead to increased saturation of calcium oxalate and formation of calcium oxalate complexes and crystals in the renal tubular lumen. Some crystals attach to the surface of renal tubular epithelial cells and further aggregate into stones, whereas others are internalized into tubular cells and then extruded into the renal interstitium, leading to marked nephrocalcinosis (Hoppe et al, 2009). Renal injury may be a consequence of direct cell toxicity from either high oxalate concentration or calcium oxalate crystals, mediated through reactive oxygen species. Renal impairment occurs from recurrent obstructing calcium oxalate stones and as a result of renal parenchymal inflammation and interstitial fibrosis from severe nephrocalcinosis (Mulay et al, 2013). With progressive renal damage, renal elimination of oxalate is impaired, leading to systemic deposition of calcium oxalate crystals, or systemic oxalosis.

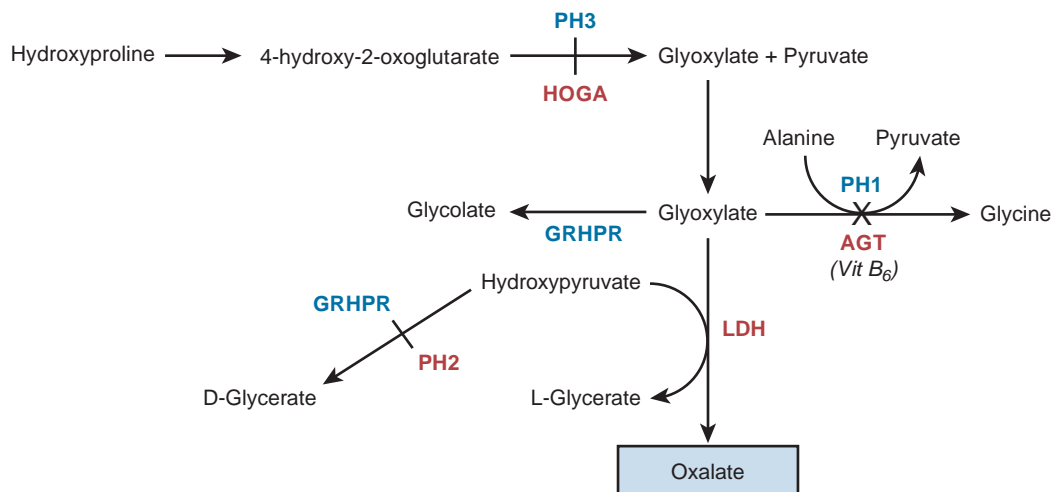

Figure 51-6. Pathway of oxalate metabolism in the liver. Defects in alanine:glyoxylate amino-transferase (AGT) are associated with primary hyperoxaluria type 1 (PH1), defects in glyoxylate reductase/hydroxypyruvate reductase (GRHPR) are associated with primary hyperoxaluria type 2 (PH2), and defects in 4-hydroxy-2-oxoglutarate aldolase (HOGA) are associated with primary hyperoxaluria type 3 (PH3). LDH, lactate dehydrogenase.

Three forms of PH have been identified (types 1, 2, and 3) that differ in the enzyme and intracellular organelle affected. The primary enzyme catalyzing glyoxylate conversion to glycine is the pyridoxal phosphate-dependent alanine-glyoxylate aminotransferase (AGT), which is synthesized in the liver peroxisome. Mutations in this gene (AGXT) result in primary hyperoxaluria type 1 (PH1), and patients with this disorder have elevated levels of oxalate and frequently glycolate. End-stage renal disease (ESRD) occurs during the second to third decade of life in most patients with PH1, making it the most aggressive form of the disease (Hoppe et al, 2009). Elucidation of the crystal structure of AGT to 2.5 Å has improved the understanding of mutations in the gene for this protein (Zhang et al, 2003). The most common mutation of AGXT results in a substitution of glycine by arginine at position 170; in the setting of a proline-to-leucine substitution at position 11 present in a polymorphic minor allele, this causes the enzyme to inappropriately target the liver mitochondria, where it is metabolically inactive, rather than the liver peroxisomes (Fargue et al, 2013a). Patients with this mutation are responsive to pyridoxine therapy because pyridoxine is metabolized to pyridoxal phosphate, an essential cofactor for AGT, which results in an increased enzyme catalytic activity and enhanced peroxisome targeting (Fargue et al, 2013b). To date, at least 178 mutations have been identified in the AGXT gene.

Primary hyperoxaluria type 2 (PH2) is associated with a defect in glyoxylate reductase/hydroxypyruvate reductase (GRHPR) in the liver, resulting in hyperoxaluric nephrolithiasis, but with a less aggressive course with regard to renal failure than PH1 (Johnson et al, 2002). Patients with PH2 have elevated urinary levels of L-glyceric acid and oxalate because reduced GRHPR enzyme activity leads to increased hydroxypyruvate and glyoxylate, which are converted by lactate dehydrogenase to L-glyceric acid and oxalate, respectively. A total of 30 mutations have been identified in the GRHPR gene (Cochat and Rumsby, 2013).

A third type of primary hyperoxaluria has recently been recognized. Primary hyperoxaluria type 3 (PH3) is caused by a defective mitochondrial enzyme, 4-hydroxy-2-oxoglutarate aldolase (HOGA), which is thought to play a role in hydroxyproline metabolism (Belostotsky et al, 2010). 4-Hydroxy-2-oxoglutarate derived from hydroxyproline is converted to pyruvate and glyoxylate in a reaction catalyzed by HOGA. However, the mechanism by which this defect leads to hyperoxaluria has not been established. Although PH3 is associated with hyperoxaluria and severe hypercalciuria, the recurrent calcium oxalate stone formation seen in early childhood may become clinically silent later in life, and there are no reports to date of progression to ESRD in these patients (Hoppe, 2012).

If untreated, PH1 inevitably leads to end-stage renal failure, which occurs by age 15 in 50% of affected patients and is associated with an overall death rate of approximately 30% (Cochat et al, 1999). Because the liver is the only organ responsible for detoxification of glyoxylate, combined liver-kidney transplantation is accepted treatment for most patients with severe PH. Reported 5-year patient survival and liver allograft survival after combined liver-kidney transplantation are 80% and 72%, respectively (Jamieson, 2005). Furthermore, the renal function of survivors reportedly remains stable over time (Cochat et al, 1999; Hoppe and Langman, 2003). Isolated kidney transplantation is the treatment of choice for patients with PH2 and ESRD, because hypoxanthine-guanine phosphoribosyl transferase (HGPRT) is not liver-specific. PH3 has not been associated with ESRD and transplantation in this setting has not been reported.

Enteric Hyperoxaluria. The most common cause of acquired hyperoxaluria is enteric hyperoxaluria. This abnormality is associated with chronic diarrheal states, by which fat malabsorption results in saponification of fatty acids with divalent cations such as calcium and magnesium, thereby reducing calcium oxalate complexation and increasing the pool of available oxalate for reabsorption (Earnest et al, 1975). The poorly absorbed fatty acids and bile salts may increase colonic permeability to oxalate, further enhancing intestinal oxalate absorption (Dobbins and Binder, 1976; Hatch and Freel, 2008). A strong relationship between fecal fat and urinary oxalate excretion has been demonstrated in patients

Figure 51-7. The relationship between fecal fat and urinary oxalate excretion in patients with steatorrhea. Diet oxalate was 300 to 500 mg/day in all but one study, in which it was 55 to 90 mg/day. Diet calcium was 500 to 900 mg/day in all studies when reported. Normal urine citrate was less than 50 mg/day in all studies, except one in which it was less than 34 mg/day. Oxalate = $2.1 \times \text{fecal fat} + 30.7$ ($r^2 = 0.4$, $n = 96$, $P < .001$). (From Worcester EM. Stones due to bowel disease. In Coe F, Favus M, Pak C, et al, editors. *Kidney stones: medical and surgical management*. New York: Lippincott-Raven; 1996. p. 883–903.)

with steatorrhea (Fig. 51-7) (Worcester, 1996). Dehydration, hypokalemia, hypomagnesiuria, hypocitraturia, and low urine pH also increase the risk of calcium oxalate stone formation in patients with chronic diarrheal syndrome. Malabsorption of any cause can lead to increased intestinal absorption of oxalate. Therefore small bowel resection, intrinsic disease, and jejunioileal bypass (Cryer et al, 1975) have all been associated with hyperoxaluria.

As the prevalence of obesity in the population has increased, bariatric surgery has become more popular and pervasive. Although jejunioileal bypass for obesity was discontinued in the past in part due to renal failure and nephrolithiasis induced by severe hyperoxaluria, modern bariatric surgery was thought to provide a safer alternative for weight loss. However, a 2005 report from the Mayo Clinic revealed two patients with oxalate nephropathy and renal failure who required dialysis and/or renal transplantation among 23 patients with enteric hyperoxaluria and calcium oxalate stones after Roux-en-Y gastric bypass surgery (Nelson et al, 2005). Since then, a number of retrospective (Asplin and Coe, 2007; Patel et al, 2009), cross-sectional (Maalouf et al, 2010), and prospective (Park et al, 2009; Duffey et al, 2010) studies have shown increased urinary oxalate excretion in non-stone-forming individuals after Roux-en-Y gastric bypass and other malabsorptive bariatric procedures. The rise in urinary oxalate was shown to develop at least 6 months after bypass surgery (Sinha et al, 2007). To varying degrees, the increase in urinary oxalate was offset by a decline in urinary calcium and uric acid, leading to conflicting effects on urinary saturation of calcium oxalate.

Despite some variation in the observed effect on urinary analytes, an increased rate of stone formation has been reported after gastric bypass surgery. Using a claims database, Matlaga and associates (2009) found that 7.65% of 4639 patients after Roux-en-Y gastric bypass surgery versus 4.63% of 4639 obese controls were diagnosed with kidney stones ($P < .0001$) after a median observation period of 4.6 years and 4.1 years, respectively. The risk appears to be limited to patients undergoing gastric bypass surgery, as a similar claims study demonstrated a higher rate of stone formation in a control group compared to a group of patients undergoing gastric banding (5.97% vs. 1.49%, respectively) (Semins et al, 2009). Indeed, a comparison of 27 patients after Roux-en-Y gastric bypass surgery with 12 patients after gastric banding revealed higher urinary oxalate, lower urinary calcium, and marginally lower urinary citrate in the bypass group compared to the banding group, suggesting that

gastric banding is not associated with malabsorption and enteric hyperoxaluria (Penniston et al, 2009).

The etiology of the hyperoxaluria observed after gastric bypass surgery has not been fully elucidated. Although loss of *O. formigenes*, an oxalate-degrading bacterium that resides in the intestinal tract, has been suggested as a possible source, the presence of low *O. formigenes* colonization levels in morbidly obese patients prior to Roux-en-Y gastric bypass surgery argues against this hypothesis (Duffey et al, 2011). Moreover, no significant difference in *O. formigenes* colonization was found between 10 post-bariatric surgery patients and 13 morbidly obese controls (40% vs. 15%, respectively) (Froeder et al, 2012). However, the urinary oxalate response to an oral oxalate load was more pronounced in patients after bariatric surgery than before and greater than the response in morbidly obese controls, suggesting that hyperoxaluria observed after bariatric surgery is due to increased intestinal absorption of dietary oxalate. Indeed, Kumar and colleagues (2011) prospectively studied 11 morbidly obese subjects before and 6 and 12 months after bariatric surgery (Roux-en-Y gastric bypass or biliopancreatic diversion-duodenal switch) and found significant increases in plasma oxalate, urine calcium oxalate supersaturation, and fecal fat excretion at both time points after surgery. Unlike previous studies, no significant increase in urinary oxalate or decline in urinary calcium was observed, likely as a result of aggressive calcium supplementation postsurgery. However, urinary oxalate was elevated in a 24-hour urine collection obtained after an oral oxalate load at both 6 and 12 months. These findings suggest that the etiology of the hyperoxaluria and increased stone risk associated with bariatric surgery is at least in part due to malabsorption and enteric hyperoxaluria.

Dietary Hyperoxaluria. Overindulgence in oxalate-rich foods such as nuts, chocolate, brewed tea, spinach, potatoes, beets, and rhubarb can result in hyperoxaluria in otherwise normal individuals. The contribution of dietary oxalate to urinary oxalate excretion can range from 24% to 42% (Holmes et al, 2001). In addition, severe calcium restriction may result in reduced intestinal binding of oxalate and increased intestinal oxalate absorption. Ascorbic acid supplementation has been shown to increase urinary oxalate levels by in vivo conversion to oxalate (Traxer et al, 2003), although increased clinical rates of stone formation have not been unequivocally linked to ascorbic acid use (Curhan et al, 1996, 1999).

Recent studies have also implicated *O. formigenes*, an oxalate-degrading intestinal bacterium, as a potential modulator of intestinal oxalate levels (Duncan et al, 2002). Stone formers were found to have reduced levels or absent colonization of *O. formigenes* compared with non-stone-forming control subjects, and individuals lacking the bacteria have been shown to have higher urinary oxalate levels (Sidhu et al, 1999; Mikami et al, 2003; Troxel et al, 2003). In a recent large case-control study of age- and gender-matched recurrent calcium oxalate stone formers ($n = 274$) and normal subjects ($n = 259$), 17% of stone formers and 38% of normal subjects tested positive for *O. formigenes* (Kaufman et al, 2008). Controlling for confounding factors, the OR for colonization (case vs. control) was 0.3 (95% CI 0.2 to 0.5). Interestingly, median urinary oxalate levels did not differ between those with or without *O. formigenes* colonization. Cystic fibrosis patients, many of whom are exposed to prolonged antibiotic use, have also been shown to have absence of *O. formigenes* from the intestinal tract and corresponding elevated urinary oxalate levels (Sidhu et al, 1998). Likewise, *O. formigenes* colonization was compared between a group of patients with *Helicobacter pylori* treated with antibiotics and a group of patients without *H. pylori*. Among 12 patients positive for *O. formigenes* not treated with antibiotics, 92% of patients remained *O. formigenes*-positive at 1 and 6 months. In contrast, among 19 subjects with *H. pylori* who received antibiotics, only 36.8% remained colonized with *O. formigenes* 1 and 6 months after treatment (Kharlam et al, 2011). These findings highlight the potential prolonged effect of antibiotic therapy on intestinal colonization of *O. formigenes* and a potential role in modulating stone risk.

Idiopathic Hyperoxaluria. Several studies have suggested that mild hyperoxaluria is as important a factor as hypercalciuria in the pathogenesis of idiopathic calcium oxalate stones (Menon, 1986;

Robertson and Hughes, 1993). In some populations, such as those inhabiting the Arabian Peninsula, the prevalence of calcium-containing stones is considerably higher than in the West despite the almost complete absence of hypercalciuria (Robertson and Hughes, 1993). Hyperoxaluria is implicated as the predominant risk factor in this population.

Abnormalities in the metabolism and transport of oxalate may contribute to calcium oxalate nephrolithiasis. Baggio and colleagues (1986) detected a higher rate of oxalate flux across the red blood cell membrane at steady state in 114 patients with a history of calcium oxalate kidney stones compared with control subjects. Treatment with oral hydrochlorothiazide (50 mg/day), amiloride (5 mg/day), or both restored normal or nearly normal red blood cell oxalate exchange in all of the patients who initially demonstrated increased rates. Up to 50% of the time, however, the abnormality in red blood cell oxalate transport is not associated with hyperoxaluria. Furthermore, Motola and colleagues (1992) found high rates of oxalate flux in non-calcium oxalate stone formers as well, thus leading some to question the importance of this mechanism in calcium oxalate stone formation.

Hyperuricosuria

Hyperuricosuria is defined as urinary uric acid exceeding 600 mg/day. Up to 10% of calcium stone formers have high urinary uric acid levels as an isolated abnormality, but it is found in combination with other metabolic abnormalities in up to 40% of calcium stone formers (Preminger, 1992). The mechanism by which hyperuricosuria induces calcium oxalate stones is not completely elucidated. Hyperuricosuria has been postulated to increase urinary levels of monosodium urate, which in turn promotes calcium oxalate crystallization through heterogeneous nucleation, or epitaxial crystal growth (Pak and Arnold, 1975). In addition, uric acid has been shown to reduce the effectiveness of naturally occurring macromolecular inhibitors of crystallization (Robertson et al, 1976; Zerwekh et al, 1983). However, some investigators dispute the effect of monosodium urate and attribute the effect of uric acid on calcium oxalate stone formation to the simple process of "salting out," whereby the solubility of calcium oxalate in solution is decreased (Ryall et al, 1991; Grover and Ryall, 1994).

The most common cause of hyperuricosuria is increased dietary purine intake. However, acquired and hereditary diseases may also be accompanied by hyperuricosuria, including gout, myeloproliferative and lymphoproliferative disorders, multiple myeloma, secondary polycythemia, pernicious anemia, hemolytic disorders, hemoglobinopathies and thalassemia, complete or partial HGPRT deficiency, overactivity of phosphoribosylpyrophosphate synthetase, and hereditary renal hypouricemia (Halabe and Sperling, 1994). The identification of a urate transporter, the anion exchanger URAT1, in the proximal renal tubule may provide new insight into the causes of hyperuricosuria (Enomoto et al, 2002; Ichida et al, 2004). Mutations in SLC22A12, the gene encoding URAT1, have been shown to cause hyperuricosuric hypouricemia (renal uric acid leak) along with exercise-induced acute renal failure and a high risk of kidney stones (Enomoto et al, 2002; Tanaka et al, 2003; Ichida et al, 2004; Iwai et al, 2004).

Not all evidence supports a role for uric acid in calcium oxalate stone formation. Among 3350 male and female participants (2237 stone formers and 1113 non-stone formers) from three large cohort studies who collected 24-hour urine specimens for stone risk analysis, after adjusting for other urinary parameters, urinary uric acid excretion was significantly inversely associated with incident kidney stone formation in men, marginally inversely associated in younger women, and not associated in older women (Curhan and Taylor, 2008). On the other hand, a randomized trial among hyperuricosuric, normocalciuric calcium oxalate stone formers demonstrated a greater than twofold reduction in stone recurrence rates among patients randomized to allopurinol versus those taking placebo (Ettinger et al, 1986). However, the mechanism of action of allopurinol in reducing stone recurrence rates cannot be definitively attributed to its effect in reducing urinary uric acid.

Hypocitraturia

Hypocitraturia is an important and correctable abnormality associated with nephrolithiasis that exists as an isolated abnormality in up to 10% of calcium stone formers and is associated with other abnormalities in 20% to 60% of stone formers (Pak, 1994; Levy et al, 1995). Citrate is an important inhibitor that can reduce calcium stone formation by several mechanisms. First, citrate reduces urinary saturation of calcium salts by complexing with calcium (Pak et al, 1982). Second, citrate directly prevents spontaneous nucleation of calcium oxalate (Sakhaee et al, 1987). Third, citrate inhibits agglomeration and sedimentation of calcium oxalate crystals (Kok et al, 1986; Tiselius et al, 1993a, 1993b), as well as the growth of calcium oxalate and calcium phosphate crystals (Meyer and Smith, 1975). Finally, normal urinary citrate levels can enhance the inhibitory effect of Tamm-Horsfall glycoprotein (Hess et al, 1993).

Hypocitraturia is defined as a urinary citrate level less than 320 mg/day. Acid-base state is the primary determinant of urinary citrate excretion. Metabolic acidosis reduces urinary citrate levels secondary to enhanced renal tubular reabsorption and decreased synthesis of citrate in peritubular cells (Hamm, 1990). A study comparing normal subjects and stone formers noted comparable mean serum citrate levels and filtered citrate loads in the two groups; however, 24-hour urinary citrate and the fasting citrate-to-creatinine ratio were significantly reduced and mean tubular reabsorption of citrate was significantly increased in the stone formers compared with control subjects (Minisola et al, 1989).

Indirect evidence for a primarily renal etiology of hypocitraturia comes from a study comparing intestinal absorption of citrate in idiopathic hypocitraturic stone formers and normal subjects (Fegan et al, 1992). Oral ingestion of citrate was followed by rapid and efficient absorption in both groups, with 96% to 98% absorbed within 3 hours. As such, hypocitraturia is unlikely to arise from impaired gastrointestinal absorption of citrate in stone formers without overt bowel disease.

Low urinary citrate results from a variety of pathologic states associated with acidosis. Distal RTA is characterized by high urine pH (>6.8), high serum chloride, and low serum bicarbonate and potassium (Preminger et al, 1985). The inability to acidify urine in response to an oral acid (ammonium chloride) load confirms the diagnosis of RTA. Chronic diarrheal states cause intestinal alkali loss in the stool with subsequent systemic acidosis and hypocitraturia (Rudman et al, 1980). Excessive animal protein can provide an acid load, reducing citrate levels (Breslau et al, 1988). Indeed, a metabolic study evaluating the effect of a high-protein, low-carbohydrate diet demonstrated a significant reduction in urinary citrate and pH, likely as a result of low citrus and high animal protein intake (Reddy et al, 2002). Diuretics such as thiazides induce hypokalemia and intracellular acidosis (Nicar et al, 1984). Angiotensin-converting enzymes can cause hypocitraturia independently of systemic acidosis or hypokalemia, perhaps as a result of intracellular acidosis (Melnick et al, 1998). Finally, strenuous exercise may induce lactic acidosis (Sakhaee et al, 1987). However, hypocitraturia may also represent an isolated abnormality unrelated to an acidotic state.

Citrate levels in the urine increase in alkalotic states, as well as with elevated levels of PTH, estrogen, magnesium, calcitonin, and vitamin D (Hamm and Hering-Smith, 2002).

Low Urine pH

At low urine pH (<5.5), the undissociated form of uric acid predominates, leading to uric acid and/or calcium stone formation. Calcium oxalate stones form as a result of heterogeneous nucleation with uric acid crystals (Coe and Kavalach, 1974; Pak et al, 1976). Any disorder leading to low urine pH may predispose to stone formation. Chronic metabolic acidosis can lead to low urine pH, hypercalciuria, and hypocitraturia. Acidosis increases bone resorption and produces renal calcium leak (Lemann, 1999; Lemann et al, 2003). "Gouty diathesis," or idiopathic low urine pH, refers to a stone-forming propensity characterized by low urine pH of

unknown etiology with or without associated gouty arthritis (Levy et al, 1995).

Renal Tubular Acidosis

RTA is a clinical syndrome characterized by metabolic acidosis resulting from defects in renal tubular hydrogen ion secretion or bicarbonate reabsorption. There are three types of RTA: 1, 2, and 4. Type 1 (distal) RTA is of particular significance to urologists not only because it is the most common form of RTA but also because it is the form of RTA most frequently associated with stone formation, which occurs in up to 70% of affected individuals (Van den Berg et al, 1983). Indeed, symptoms associated with nephrolithiasis led to the initial diagnosis of RTA in upward of 50% of cases (Van den Berg et al, 1983).

Acid-base balance is maintained by the kidney through several mechanisms involving both the proximal and distal nephron. Because bicarbonate is freely filtered at the glomerulus, the kidney must reabsorb or regenerate nearly all of the filtered bicarbonate each day (≈ 4500 mmol) to maintain its buffering capacity, a process that takes place primarily in the proximal renal tubule (Pohlman et al, 1984). Furthermore, the kidney must excrete excess acid, which accumulates from the breakdown of carbohydrates, fats, and proteins and as a result of bicarbonate loss in the stool. Net acid excretion occurs in the distal renal tubule. A defect in either bicarbonate reabsorption or acid excretion will lead to metabolic acidosis.

Filtered bicarbonate (HCO_3^-) is almost completely reabsorbed in the proximal renal tubule through an indirect mechanism involving hydrogen (H^+) secretion (Laing et al, 2005). Carbonic anhydrase in the tubular cells generates H^+ and HCO_3^- , thereby providing H^+ ions that are secreted into the tubular lumen by way of a Na^+/H^+ exchanger in the apical membrane. Sodium (Na^+) pumped out of the proximal tubule cell by the sodium-potassium adenosine triphosphatase (Na^+/K^+ -ATPase) exchanger located in the basolateral membrane drives the Na^+/H^+ exchanger in the apical membrane by reducing intracellular sodium. At the same time, HCO_3^- is transferred via a basolateral $\text{Na}^+/\text{HCO}_3^-$ cotransporter into the plasma. Additional active H^+ secretion into the tubular lumen is accomplished by an apical H^+ -ATPase. Luminal H^+ ion combines with filtered HCO_3^- to form H_2CO_3 , which is rapidly converted by another form of carbonic anhydrase to H_2O and CO_2 , which diffuses back in to the cell. The net effect is transepithelial HCO_3^- absorption without causing net H^+ secretion or a significant change in urinary pH.

The distal nephron is the site of net elimination of H^+ , although 5% to 10% of filtered bicarbonate is also reabsorbed there in a manner similar to the proximal nephron. Hydrogen binds with urinary buffers such as titratable acid (mainly phosphate) and ammonia, allowing net elimination of hydrogen in the form of NH_4^+ . H^+ excretion occurs through active secretion from α -intercalated cells. These cells secrete H^+ into the distal tubule using H^+ -ATPase and a H^+/K^+ -ATPase exchanger (Laing et al, 2005). The intercalated cells also have a $\text{Cl}^-/\text{HCO}_3^-$ anion exchanger that transports HCO_3^- into the blood. These active pumps generate a 1000:1 hydrogen ion gradient between the cell and the tubular lumen, allowing reduction of urine pH to as low as 4.5 (Kinkead and Menon, 1995). Another contributing factor is the lack of luminal carbonic anhydrase that prevents the rapid dissociation of carbonic acid catalyzed by the enzyme.

Distal and proximal RTA occur as a result of impairment of net excretion of acid into the urine (distal or type 1) or of reabsorption of bicarbonate (proximal or type 2). Distinction between these abnormalities provides the basis for classification of RTA into proximal or distal, although both share the characteristic findings of hyperchloremic metabolic acidosis associated with inappropriately high urinary pH.

Type 1 (Distal) Renal Tubular Acidosis. Type 1 RTA comprises a syndrome of abnormal collecting duct function characterized by inability to acidify the urine in the presence of systemic acidosis. The classic findings include hypokalemic, hyperchloremic,

non-anion gap metabolic acidosis along with nephrolithiasis, nephrocalcinosis, and elevated urine pH (>6.0). Patients with incomplete RTA also demonstrate defective renal acid excretion manifested as failure to lower urine pH below 5.5 after an acid load, but they do not manifest metabolic acidosis and consequently have normal serum electrolytes (Osther et al, 1989).

Patients with distal RTA commonly present as adults with symptoms of nephrolithiasis (Caruana and Buckalew, 1988). However, children comprise a third of affected individuals, and they often present with vomiting or diarrhea, failure to thrive, or growth retardation. The most common stone composition associated with distal RTA is calcium phosphate as a result of hypercalciuria, hypocitraturia, and increased urinary pH (Van den Berg et al, 1983; Pohlman et al, 1984). The metabolic acidosis promotes bone demineralization, which leads to secondary hyperparathyroidism and hypercalciuria. Profound hypocitraturia, perhaps the most important factor in stone formation in this setting, is due to impaired citrate excretion as a result of metabolic acidosis but may also be related to abnormal renal tubular citrate transport or migration of citrate into the mitochondria as a result of intracellular acidosis (Osther et al, 1989; Kinkead and Menon, 1995).

Distal RTA occurs as a consequence of dysfunction of the α -type intercalated cells, which secrete protons into the urine via an apical H^+ -ATPase that is coupled to an anion exchanger (AE1) located at the basolateral membrane (Fig. 51-8) (Karet, 2002). Mutations in three genes in the α -type intercalated cells have been implicated in hereditary distal RTA; *SLC4A1* encodes the AE1 Cl^-/HCO_3^- anion exchanger, and *ATP6V1B1* and *ATP6V0A4* encode the B1 and A4 subunits, respectively, of H^+ -ATPase. A fourth gene, *CA2*, encodes carbonic anhydrase II, which is found in the proximal tubule, the loop of Henle, and the α -intercalated cells of the collecting duct. Because carbonic anhydrase II affects bicarbonate reabsorption as well as H^+ secretion, mutations in *CA2* present a mixed pattern of proximal and distal RTA (Batlle and Haque, 2012).

Distal RTA is a heterogeneous disorder that may be hereditary, idiopathic, or acquired (Laing et al, 2005). Although most cases of distal RTA are sporadic, both autosomal dominant and autosomal recessive patterns of inheritance have been identified. The inherited forms of distal RTA are associated with growth retardation, nephrocalcinosis, renal calculi, and hypokalemic metabolic acidosis, but the phenotype is usually more severe in the autosomal recessive form of the disease. Autosomal recessive distal RTA also tends to occur earlier in life and is additionally associated with mental retardation and sensorineural hearing loss or deafness.

Mutations in the *SLC4A1* gene are most commonly associated with the autosomal dominant form of distal RTA, which can present in the complete or incomplete form, although an autosomal recessive form associated with a mutation in this gene is endemic in

Southeast Asia. This form of distal RTA, which is always complete, is commonly associated with hemolytic anemia and severe hypokalemia (Batlle and Haque, 2012). Hearing loss is not usually a feature of mutations in the *SLC4A1* gene.

Mutations in the *ATP6V1B1* and *ATP6V0A4* genes encoding H^+ -ATPase have been primarily associated with autosomal recessive distal RTA (Batlle et al, 2006). Although mutations in *ATP6V1B1* have been implicated in RTA and severe childhood deafness, mutations in *ATP6V0A4* have been associated with a milder form of hearing loss that occurs later, in early adulthood (Karet et al, 1999; Batlle et al, 2006).

Most mutations in the *CA2* gene have been identified in patients of Arabian origin. *CA2* mutations are recessive and lead to a mixed proximal-distal RTA picture characterized by bicarbonate wasting, inability to acidify the urine below pH 5.5, and reduced NH_4^+ excretion (Batlle and Haque, 2012). Carbonic anhydrase II catalyzes the hydration of CO_2 to H^+ and HCO_3^- .

Secondary distal RTA in sporadic cases is commonly associated with autoimmune diseases such as Sjögren syndrome and systemic lupus erythematosus, and it occurs more frequently in women than men (Buckalew, 1989). Secondary RTA is also associated with obstructive uropathy, pyelonephritis, acute tubular necrosis, hyperparathyroidism, and idiopathic hypercalciuria.

Type 2 (Proximal) Renal Tubular Acidosis. Proximal RTA is characterized by a defect in HCO_3^- reabsorption associated with initial high urine pH that normalizes as plasma HCO_3^- decreases and the amount of filtered HCO_3^- falls (Laing et al, 2005). With reduced capacity of the proximal tubule to reclaim filtered HCO_3^- , more HCO_3^- is delivered to the distal tubule, which has a limited capacity for bicarbonate reabsorption. Consequently, bicarbonaturia ensues, resulting in reduced net acid excretion and metabolic acidosis. As the filtered HCO_3^- load declines with progressive metabolic acidosis, less bicarbonate reaches the distal tubule until eventually the capacity of the distal tubule is sufficient to handle the load and no further bicarbonate is lost. At steady state, serum HCO_3^- is low (15 to 18 mEq/L) and urine pH is acidic (<5.5).

This syndrome is usually associated with generalized defects in proximal tubule function similar to Fanconi syndrome, with loss of glycogen, protein, uric acid, and phosphate (Rocher and Tannen, 1986). Nephrolithiasis is uncommon in this disorder owing to relatively normal urinary citrate excretion (Laing et al, 2005). The clinical manifestations of proximal RTA include growth retardation and hypokalemia in children resulting from metabolic acidosis. Metabolic bone disease is seen more frequently with proximal RTA because of associated abnormalities in vitamin D metabolism and hypophosphatemia (Kinkead and Menon, 1995).

Most cases of proximal RTA are sporadic, but inherited diseases associated with proximal RTA have been described. In humans and terrestrial vertebrates, the kidneys control systemic pH in part by absorbing filtered HCO_3^- in the proximal tubule via an electrogenic Na^+/HCO_3^- cotransporter (NBCe1/SLC4A4) located in the basolateral membrane of the proximal tubule. Homozygous point mutations in *NBCe1* cause proximal RTA, glaucoma, and cataracts (Igarashi et al, 1999). Other mutations in this gene have been identified that cause voltage- and Na^+ -dependent transport abnormalities, thereby causing both insufficient HCO_3^- reabsorption by the kidney (proximal RTA) and inappropriate anterior chamber fluid transport (glaucoma) (Dinour et al, 2004).

Carbonic anhydrase II catalyzes the hydration/dehydration of CO_2 and H_2CO_3 and is expressed in the renal proximal tubule, loop of Henle, and intercalating cells of the collecting duct, as well as in brain glial cells and bone osteoclasts (Laing et al, 2005). Deficiency of carbonic anhydrase II (carbonate hydrolyase, EC 4.2.1.1) is the primary defect in the syndrome of osteopetrosis, proximal RTA, and cerebral calcification. Fortunately, this is a rare abnormality (Sly et al, 1985; Roth et al, 1992).

Type 4 (Distal) Renal Tubular Acidosis. Type 4 RTA is associated with chronic renal damage, usually seen in patients with interstitial renal disease and diabetic nephropathy. Reduction in glomerular filtration results in hyperkalemic, hyperchloremic metabolic acidosis caused by loss of HCO_3^- in the urine and decreased

Figure 51-8. Mechanism of acidification in the collecting duct α -intercalated cell. Enzymes are shown in red and their corresponding genes in italics. The α -intercalated cells secrete H^+ into the lumen of the distal tubule and collecting duct by way of an apical H^+ -ATPase and possibly an H^+, K^+ -ATPase exchanger. Bicarbonate is transported into the blood via a Cl^-, HCO_3^- anion exchanger (AE1) on the basolateral membrane. Defects in the AE1 Cl^-, HCO_3^- anion exchanger or in H^+ -ATPase result in failure to acidify the urine in distal RTA. CA II, carbonic anhydrase II.

excretion of ammonium (Pohlman et al, 1984). Aldosterone resistance is commonly associated with type 4 RTA (Davidman and Schmitz, 1988). Because aldosterone contributes to stimulation of distal acidification and H^+ , K^+ exchange, aldosterone resistance results in decreased ammonia generation and further exacerbates hyperkalemia (Davidman and Schmitz, 1988). Patients with type 4 RTA can still generate acidic urine in response to an acid challenge.

Renal stone formation is uncommon in patients with type 4 RTA. A study comparing patients with type 4 RTA and matched subjects with a similar degree of renal impairment found that patients with type 4 RTA had significantly lower urinary pH and decreased urinary calcium excretion compared to controls (Uribarri et al, 1994). The protection against renal stone formation in these patients may be attributed to reduced renal excretion of stone-forming substances such as calcium and uric acid owing to impaired renal function.

Hypomagnesiuria

Hypomagnesiuria is a rare cause of nephrolithiasis, affecting less than 1% of stone formers as an isolated abnormality, although it can be found in conjunction with other abnormalities in 6% to 11% of cases (Levy et al, 1995; Schwartz et al, 2001). Magnesium complexes with oxalate and calcium salts, and therefore low magnesium levels result in reduced inhibitory activity. Low urinary magnesium is also associated with decreased urinary citrate levels, which may further contribute to stone formation (Preminger et al, 1989; Schwartz et al, 2001). Whether low magnesium is the cause or effect of low citrate is not clear. Low magnesium levels occur with poor dietary intake or as a result of reduced intestinal absorption associated with intestinal abnormalities producing chronic diarrheal syndrome.

Although a number of studies in rats have implicated hypomagnesiuria as a factor in stone formation (Rushton and Spector, 1982), others (Faragalla and Gershoff, 1963; Borden and Lyon, 1969; Rattan et al, 1993) have questioned the impact of magnesium (Su et al, 1991). Clinical studies regarding the role of magnesium are contradictory. Schwartz and colleagues (2001) found that hypomagnesiuric patients had higher stone recurrence rates than patients with normal urinary magnesium. However, other studies found no difference in magnesium excretion between stone patients and controls (Johansson et al, 1980; Esen et al, 1991). Of note, the lack of difference in mean magnesium levels may be a result of the small fraction of stone formers with low urinary magnesium levels.

Although magnesium has been shown to increase urinary pH, citrate, and magnesium levels and therefore to decrease urinary saturation of calcium oxalate in vitro (Khan et al, 1993) and in vivo (Curhan et al, 2001), two randomized trials comparing magnesium oxide with placebo or no treatment in stone formers failed to demonstrate clinical benefit (Wilson et al, 1984; Ettinger et al, 1988).

Uric Acid Stones

Most mammals, except humans and Dalmatians, synthesize the hepatic enzyme uricase, which catalyzes the conversion of uric acid to allantoin, the end product of purine metabolism (Yu, 1981; Bannasch et al, 2004). Consequently, humans accumulate significantly higher levels of uric acid in their blood and urine (Watts, 1976; Yu, 1981). Because allantoin is 10 to 100 times more soluble in urine than uric acid, humans are prone to uric acid stone formation. Uric acid comprises 8% to 10% of all kidney stones in the United States and up to 25% in certain regions in Germany (Maalouf et al, 2004a).

Uric acid is a weak acid with a pK_a of 5.35 at 37° C. At that pH, half of the uric acid is present as the urate salt and half as free uric acid. Because sodium urate is approximately 20 times more soluble than the free acid, the relative proportion present as free uric acid strongly determines the risk of stone formation. **Urine pH is a critical factor in determining uric acid solubility;** at pH 5, even modest amounts of uric acid exceed uric acid solubility, whereas at pH 6.5,

concentrations of uric acid exceeding 1200 mg/L remain soluble (Fig. 51-9) (Asplin, 1996). Under normal conditions, the limit of uric acid solubility is approximately 96 mg/L, a level readily exceeded by normal daily uric acid excretion, which averages 500 to 600 mg/L. Consequently, urine may reach supersaturation, particularly at pH less than 6. Low urine pH increases concentrations of sparingly soluble undissociated uric acid, which leads to direct precipitation of uric acid. Of note, uric acid and sodium urate have been implicated as nuclei for calcium oxalate stones through heterogeneous nucleation and epitaxial crystal growth, and thus low urine pH is thought to be a risk factor for uric acid, calcium oxalate, and mixed calcium and uric acid stones (Maalouf, 2011).

The process of uric acid stone formation once uric acid crystals precipitate has not been fully elucidated. Although some investigators have suggested that uric acid crystal adhesion to kidney epithelial cells (Koka et al, 2000) and inhibitors such as glycosaminoglycans (Ombra et al, 2003) may play a role in uric acid stone formation, the involvement or importance of these factors in uric acid stone formation is unclear.

The three main determinants of uric acid stone formation are low pH, low urine volume, and hyperuricosuria (Fig. 51-10). The most important pathogenetic factor is low urine pH because most patients with uric acid stones have normal uric acid excretion but invariably demonstrate persistent low urine pH (Pak et al, 2001; Sakhaee et al, 2002). Uric acid stones can develop as a result of congenital, acquired, or idiopathic causes. Congenital disorders associated with uric acid stones involve renal tubular urate transport or uric acid metabolism, leading to hyperuricosuria. Acquired causes of uric acid stones such as chronic diarrhea, volume depletion, myeloproliferative disorders, high animal protein intake, and uricosuric drugs may affect any of the three factors determining uric acid stone formation. Patients with "gouty diathesis" or idiopathic uric acid nephrolithiasis typically demonstrate decreased fractional excretion of urate and do not have gout (Maalouf et al, 2004a). Patients with idiopathic uric acid nephrolithiasis differ from those with hyperuricosuric calcium nephrolithiasis in that the former generally have normal urinary uric acid levels and acidic urine, whereas the latter have hyperuricosuria and normal urine pH (Pak et al, 2002). Patients with hyperuricosuria frequently have high urinary sodium and calcium levels leading to increased urinary saturation of sodium urate and calcium oxalate, placing them at risk for calcium oxalate stones (Sorensen and Chandhoke, 2002).

Pathogenesis of Low Urine pH

Although the pathogenesis of low urine pH in idiopathic uric acid stone formers is not known with certainty and may be multifactorial, several potential mechanisms have been proposed. Sakhaee and colleagues (2002) first observed that normouricosuric individuals with pure uric acid stones were more likely to have diabetes mellitus or to demonstrate glucose intolerance than normal individuals or those with mixed uric acid–calcium oxalate or pure calcium oxalate stones. Furthermore, when a group of normouricosuric uric acid stone formers was placed on a controlled metabolic diet, the urinary pH was lower than that of either normal volunteers or other stone formers (mixed uric acid–calcium oxalate or calcium oxalate). Further investigation revealed that the uric acid stone formers excreted less acid into the urine as ammonium and proportionately more titratable acid and less citrate in order to maintain normal overall acid-base balance. **This apparent impairment in ammonium excretion in uric acid stone formers has been putatively linked to an insulin-resistant state.**

Supporting this hypothesis, Pak and colleagues (2003) noted a higher prevalence of uric acid stones and low urinary pH among patients with non–insulin-dependent diabetes mellitus (34%) than among nondiabetic stone formers. Daudon and colleagues (2006) analyzed 2464 calculi and also found that uric acid stones comprised 36% of stones among 272 patients with type 2 diabetes mellitus but only 11% among 2192 patients without type 2 diabetes. Furthermore, uric acid stone formers have been found to share many of the characteristic features of the metabolic syndrome (a

Figure 51-9. Relationship among undissociated uric acid, total uric acid, and urinary pH. The limit of solubility of undissociated uric acid is depicted by the dotted line (≈ 100 mg/L). Two hypothetical urine pH values are considered (arrows). At low pH (e.g., 5.0), even a modest amount of total urinary uric acid will exceed its solubility. At high pH (e.g., 6.5), even massive hyperuricosuria is well tolerated. (From Maalouf NM, Cameron MA, Moe OW, et al. Novel insights into the pathogenesis of uric acid nephrolithiasis. *Curr Opin Nephrol Hypertens* 2004;13:181–9.)

condition defined by insulin resistance and high-risk atherosclerotic cardiovascular disease), including hypertriglyceridemia, hyperglycemia, obesity, and hypertension (Sakhaee et al, 2002; Pak et al, 2003). In an elegant series of experiments, Abate and colleagues (2004) performed hyperinsulinemic euglycemic clamps to measure insulin sensitivity in a diverse group of non-stone-forming normal volunteers and a group of uric acid stone formers and determined that, among normal subjects, low urine pH correlated with low rates of glucose disposal (indicating insulin resistance) in both groups, but uric acid stone formers displayed the most severe levels of insulin resistance. This association of insulin resistance with low urinary pH was further corroborated by the finding of a strong inverse association of body weight (known to be associated with peripheral insulin resistance) and urinary pH, even after adjusting for urinary sulfate (a marker of animal protein intake) (Maalouf et al, 2004b).

The mechanism by which insulin resistance leads to low urine pH has not been completely elucidated. However, insulin has been shown in vitro to promote renal ammoniogenesis from the substrate glutamine (Chobanian and Hammerman, 1987; Nissim et al, 1995) and also to stimulate the Na^+/H^+ exchanger (NHE3) in the proximal tubule, which is responsible for either the direct transport or trapping of ammonium in the urine (Kliscic et al, 2002). Impaired ammonium production or excretion as a result of insulin resistance could leave hydrogen ions unbuffered in the urine, thereby leading to reduction in urine pH (Fig. 51-11).

Acidic urine pH may also be promoted by increased endogenous uric acid production or by dietary influences. When idiopathic uric acid stone formers and normal subjects were maintained on a fixed, low acid-ash diet, net acid excretion was higher in the former group compared with the latter, implicating higher endogenous acid production (Sakhaee et al, 2002). Furthermore, when

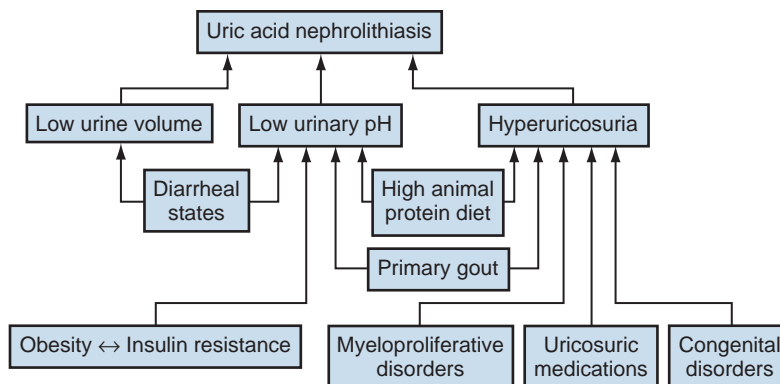

Figure 51-10. Pathophysiology and etiology of uric acid nephrolithiasis. The three major pathophysiologic mechanisms that contribute to uric acid nephrolithiasis are low urine volume, low urinary pH, and hyperuricosuria. Each of these mechanisms can result from diverse etiologies. The most important pathogenetic factor is low urinary pH. (From Maalouf NM, Cameron MA, Moe OW, et al. Novel insights into the pathogenesis of uric acid nephrolithiasis. *Curr Opin Nephrol Hypertens* 2004;13:181–9.)

Figure 51-11. Potential effects of the insulin-resistant state on the generation and secretion of ammonium in the proximal tubule. The deamination of glutamine and glutamate provides ammonia. Insulin stimulates glutamine metabolism, as well as the sodium-hydrogen exchanger NHE3. NHE3 mediates ammonium transport by either directly carrying the ammonium ion or providing the luminal hydrogen ion to trap ammonia. The end product of glutamine metabolism is α -ketoglutarate. (Modified from Maalouf NM, Cameron MA, Moe OW, et al. Novel insights into the pathogenesis of uric acid nephrolithiasis. *Curr Opin Nephrol Hypertens* 2004;13:181–9.)

controlled for urinary sulfate (a marker of acid intake), net acid excretion was higher in uric acid stone formers and in non-stone formers with type 2 diabetes compared with normal controls (Cameron et al, 2006). These studies suggest that, in the setting of impaired ammonium excretion and increased endogenous acid production resulting from obesity and/or insulin resistance, titratable acids comprise the primary urinary buffer, and while acid-base equilibrium can be maintained, it occurs at a lower pH than is typically maintained by ammonium, which has a higher pK_a .

Lipotoxicity, a process whereby fat is redistributed into nonadipocyte tissues such as the heart, liver, skeletal muscle, and pancreatic beta cells, resulting in cellular injury, has been implicated in

impaired insulin sensitivity, cardiac dysfunction, and hepatic steatohepatitis and has recently been postulated to play a role in the pathogenesis of chronic renal disease (Bagby, 2004; Weinberg, 2006; Wahba and Mak, 2007). Whether or not lipotoxicity plays a role in impaired ammonium excretion or increased endogenous acid production leading to low urine pH in uric acid stone formers is unknown (Sakhaee, 2009). However, studies in a rodent model of metabolic syndrome (Zucker diabetic fatty rat) and a proximal tubular cell line demonstrated that renal steatosis may be responsible for the reduced expression and activity of NHE3, the primary mediator of ammonium excretion (Bobulescu et al, 2008, 2009). Interestingly, recent proteomic analysis of the matrix component of uric acid stones identified 242 unique proteins among five stones, with the largest proportion of proteins involved in the inflammation and complement pathways; the most commonly involved metabolic pathways associated with these proteins were the phospholipid and fatty acid pathways (Jou et al, 2012).

Dietary content also plays a role in determining urine acidity. Breslau and colleagues (1988) evaluated 15 normal subjects in a three-way randomized, crossover study involving three 12-day phases of study in which subjects were maintained on a controlled metabolic diet containing vegetable protein, vegetable and egg protein, or animal protein, with increasing sulfate content, respectively, in the three diets. As the fixed acid content of the diets increased, urinary calcium excretion increased from 103 mg/day on the vegetarian diet to 150 mg/day on the animal protein diet ($P < .02$). Moreover, the animal protein-rich diet was associated with the highest excretion of undissociated uric acid and lowest excretion of citrate because of the reduction in urinary pH. Urinary crystallization studies revealed that the animal protein diet, when matched for electrolyte composition and quantity of protein with the vegetarian diet, conferred an increased risk of uric acid stones, but because of opposing factors, not of calcium oxalate or calcium phosphate stones.

Hyperuricosuria

Hyperuricosuria is defined as urinary uric acid exceeding 600 mg/day. Hyperuricosuria predisposes to uric acid stone formation by causing supersaturation of the urine with respect to sparingly soluble undissociated uric acid. Patients with gout and urinary uric acid levels less than 600 mg/day had significantly fewer stones than those with uric acid levels greater than 1000 mg/day (Hall et al, 1967; Yu and Gutman, 1967). The causes of hyperuricosuria have been discussed previously but include dietary factors, as well as acquired and hereditary diseases and defects in the urate transporter.

Low Urinary Volume

All conditions that contribute to low urinary volume increase the risk of uric acid supersaturation. [Borghi and colleagues \(1993\)](#) noted high uric acid relative supersaturation in workers exposed to hot temperatures compared with those working in normal temperatures. Likewise, high rates of uric acid stone formation have been found in populations living in warmer climates such as Israel ([Shekarriz and Stoller, 2002](#)).

Cystine Stones

Cystinuria is an inherited autosomal recessive disorder (or rarely autosomal dominant with incomplete penetrance) characterized by a defect in intestinal and renal tubular transport of dibasic amino acids, resulting in excessive urinary excretion of cystine ([Ng and Stroom, 1999, 2001](#)). Although the defect also results in high urinary concentrations of lysine, ornithine, and arginine, the poor solubility of cystine leads to stone formation. Cystine is a dimer, composed of two cysteine molecules linked via a disulfide bond. Cystine is much less soluble than cysteine and is responsible for cystine stone formation. Cystine stones are rare, occurring in the United States and Europe with an incidence of only 1 in 1000 to 1 in 17,000 ([Caballo-Tomas et al, 1999; Knoll et al, 2005](#)). In children, cystinuria is the cause of up to 10% of all stones ([Faerber, 2001; Erbağci et al, 2003; Knoll et al, 2005](#)).

Under normal conditions amino acids are freely filtered by the glomerulus and almost completely reabsorbed in the renal proximal tubule. Cystine and the other dibasic amino acids are transported across the apical membrane of the renal proximal tubule by a sodium-independent heteromeric amino acid transporter in exchange for neutral amino acids. Cystine is reduced intracellularly to cysteine, thereby providing a favorable gradient for continued cystine reabsorption ([Broer, 2008](#)). In cystinuria, the defect in cystine transport results in high urinary levels. Several factors determine the solubility of cystine, including cystine concentration, pH, ionic strength, and urinary macromolecules. The main contributor to cystine crystallization is supersaturation because there is no specific inhibitor of cystine crystallization in the urine ([Pak and Fuller, 1983](#)). Because of the poor solubility of cystine in urine, precipitation of cystine and subsequent stone formation occur at physiologic urine conditions ([Joly et al, 1999](#)). The solubility of cystine is highly pH dependent, with solubilities of 300 mg/L, 400 mg/L, and 1000 mg/L at pH levels of 5, 7, and 9, respectively ([Dent and Senior, 1955](#)). Ionic strength also influences solubility, and as much as 70 mg of additional cystine can be dissolved in each liter of solution as ionic strength increases from 0.005 to 0.3 ([Pak and Fuller, 1983](#)). Macromolecules such as colloid also increase cystine solubility, although the mechanism is unclear ([Pak and Fuller, 1983](#)). Therefore cystine is more soluble in urine than in synthetic solution ([Fig. 51-12](#)).

Other factors may contribute to stone formation in cystinuric patients as well. [Sakhae and colleagues \(1989\)](#) evaluated 27 patients with documented cystine nephrolithiasis and identified hypercalciuria in 19%, hyperuricosuria in 22%, and hypocitraturia in 44%, which could contribute to formation of not only cystine stones but also calcium or mixed calcium-cystine stones.

The genetics of cystinuria have been studied extensively. Two genes involved in the disease have been identified: *SLC3A1* ([Pras et al, 1994](#)), which resides on the short arm of chromosome 2 and codes for a 663-amino acid heavy subunit (rBAT) of the cystine transporter, and *SLC7A9* ([Feliubadaló et al, 1999](#)), which is located on the long arm of chromosome 19 and codes for a 487-amino acid light subunit (b⁰+AT) of the cystine transporter. The two subunits form a heterodimer that resides in the apical membrane of the proximal tubule cells. As of 2010, a total of 133 and 95 mutations had been reported in the *SLC3A1* and the *SLC7A9* genes, respectively ([Chillaron et al, 2010](#)).

Historically, three types of cystinuria have been recognized in humans—type I, type II, and type III—on the basis of levels of urinary cystine in obligate heterozygote parents of the proband

Figure 51-12. Cystine solubility in urine. Each point represents solubility of cystine determined in a separate urine sample by incubation with an excess of solid cystine. The solubility curve of [Dent and Senior \(1955\)](#) and that obtained in a 5-mM sodium cacodylate solution are plotted for comparison. (From [Pak CY, Fuller CJ. Assessment of cystine solubility in urine and of heterogeneous nucleation. J Urol 1983;129:1066–70.](#))

([Rosenberg et al, 1966](#)). However, this classification correlated poorly with molecular findings, and therefore it has been revised by the International Cystinuria Consortium (ICC) to take into account the chromosomal localization of the mutation: type A (chromosome 2), type B (chromosome 19), and type AB (both chromosomes) ([Dello Strologo et al, 2002](#)). Homozygotes with the condition exhibit urinary cystine levels as high as 2000 $\mu\text{mol/g}$ of creatinine. Review by the ICC revealed that the average age at first stone diagnosis was 12.2 years, with a mean number of stone episodes of 0.42 and 0.21 per year occurring in men and women, respectively ([Dello Strologo et al, 2002](#)). Although mean urinary cystine levels are significantly higher in heterozygotes with type B abnormalities (475 $\mu\text{mol/g}$ creatinine) compared with those with type A abnormalities (70 $\mu\text{mol/g}$ creatinine), there is no difference in stone formation between the two groups, and, in fact, stone formation is uncommon ([Dello Strologo et al, 2002](#)).

Although stone formers in general have been found to have a higher likelihood of developing chronic kidney disease ([Worcester et al, 2006b](#)), cystine stone formers have been shown to have lower creatinine clearances than other stone formers ([Worcester et al, 2006a](#)). A potential explanation for this finding is the observation

that cystinurics undergo more open surgical procedures, including nephrectomy, than their calcium oxalate stone-forming counterparts (Assimos et al, 2002). Histologically, these patients have been observed to have dilated ducts of Bellini plugged by cystine crystals as well as evidence of cortical glomerulosclerosis and interstitial fibrosis (Evan et al, 2006b).

Infection Stones

Infection stones are composed primarily of magnesium ammonium phosphate hexahydrate ($\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$) but may in addition contain calcium phosphate in the form of carbonate apatite ($\text{Ca}_{10}[\text{PO}_4]_6 \cdot \text{CO}_3$). A Swedish geologist discovered magnesium ammonium phosphate in guano and named it "struvite" after his mentor, naturalist H.C.G. von Struve (Griffith and Osborne, 1987). Brown (1901) first theorized that bacteria split urea, thereby setting up the condition for stone formation, and he later isolated *Proteus vulgaris* from a stone. Hager and Magath (1925) postulated that a bacterial enzyme hydrolyzed urea, and Sumner (1926) isolated urease from *Canavalia ensiformis*. It is now well established that struvite stones (magnesium ammonium phosphate) occur only in association with urinary infection by urea-splitting bacteria (Griffith and Musher, 1973).

Pathogenesis

The process of urealys provides an alkaline urinary environment and sufficient concentrations of carbonate and ammonia to induce the formation of infection stones. Because urease is not present in sterile human urine, infection with urease-producing bacteria is a prerequisite for the formation of infection stones. A cascade of chemical reactions generates the conditions conducive to the formation of infection stones. Urinary urea, a constituent of normal urine, is first hydrolyzed to ammonia and carbon dioxide in the presence of bacterial urease:

The alkaline urine that results from this reaction (pH 7.2 to 8.0) favors the formation of ammonium:

Under physiologic conditions, the alkaline urine would prevent further generation of ammonium. However, in the presence of urease, ammonia continues to be produced, further increasing urinary pH. The alkaline environment also promotes the hydration of carbon dioxide to carbonic acid, which then dissociates into HCO_3^- and H^+ . Further dissociation of HCO_3^- yields carbonate and another hydrogen ion:

The dissociation of hydrogen phosphate under alkaline conditions provides phosphate, thereby completing the generation of constituent ions for infection stone formation:

This chemical cascade, along with physiologic concentrations of magnesium, provides the constituents necessary for precipitation of struvite. In addition, the concentrations of calcium, phosphate, and carbonate allow precipitation of carbonate apatite and hydroxyapatite, thereby comprising the components of infection stones (Fig. 51-13).

Figure 51-13. Schematic depicting concurrent events leading to struvite stone formation. (From Johnson DB, Pearle MS. Struvite stones. In: Stoller ML, Meng MV, editors. Urinary stone disease: the practical guide to medical and surgical management. Totowa [NJ]: Humana Press; 2007.)

Although infection stones are a direct result of persistent or recurrent infection with urease-producing bacteria, they may also be associated with or exacerbated by urinary obstruction or stasis (Bichler et al, 2002). Therefore growth of infection stones can progress at a rapid rate.

Bacteriology

Although the family Enterobacteriaceae comprises the majority of urease-producing pathogens, a variety of gram-positive and gram-negative bacteria and some yeasts and *Mycoplasma* species have the capacity to synthesize urease (Table 51-3). The most common urease-producing pathogens are *Proteus*, *Klebsiella*, *Pseudomonas*, and *Staphylococcus* species, with *Proteus mirabilis* the most common organism associated with infection stones. Although *Escherichia coli* is a common cause of urinary tract infections, only rare species of *E. coli* produce urease (Bichler et al, 2002).

Bacteria may be involved in stone formation by damaging the mucosal layer of the urinary tract, resulting in both increased bacterial colonization and crystal adherence (Parsons et al, 1984; Grenabo et al, 1988; Djojodimedjo et al, 2013). It has been proposed that ammonium, generated as a result of urealys, may alter the glycosaminoglycan layer present on the surface of the transitional cell layer and significantly increase bacterial adherence to normal bladder mucosa, further exacerbating infection risk (Parsons et al, 1984). In addition, a study in rats found that injury to the bladder mucosa increased crystal adherence to the bladder wall, a process that was potentiated by the presence of common bacteria such as *Proteus*, *E. coli*, *Enterococcus*, and *Ureaplasma urealyticum* (Grenabo et al, 1988). Another potential mechanism for increased stone formation in the presence of bacteria is the finding that particular bacteria, such as *E. coli* and *Proteus*, may alter the activity of urokinase and sialidase, whereas organisms not typically associated with infection stones do not (du Toit et al, 1992). This altered enzymatic activity may explain the frequent association of *E. coli* with stone formation despite lacking urease activity (Holmgren et al, 1989).

TABLE 51-3 Organisms That May Produce Urease

ORGANISMS	USUALLY (>90% OF ISOLATES)	OCCASIONALLY (5%-30% OF ISOLATES)
Gram-negative	<i>Proteus rettgeri</i> <i>Proteus vulgaris</i> <i>Proteus mirabilis</i> <i>Proteus morgani</i> <i>Providencia stuartii</i> <i>Haemophilus influenzae</i> <i>Bordetella pertussis</i> <i>Bacteroides corrodens</i> <i>Yersinia enterocolitica</i> <i>Brucella</i> species	<i>Klebsiella pneumoniae</i> <i>Klebsiella oxytoca</i> <i>Serratia marcescens</i> <i>Haemophilus parainfluenzae</i> <i>Bordetella bronchiseptica</i> <i>Aeromonas hydrophila</i> <i>Pseudomonas aeruginosa</i> <i>Pasteurella</i> species

From Gleeson MJ, Griffith DP. Infection stones. In: Resnick MI, Pak CYC, editors. Urolithiasis: a medical and surgical reference. Philadelphia: Saunders; 1990. p. 115.

Epidemiology

Although infection stones comprise only 5% to 15% of all stones (Levy et al, 1995), they have been thought to be the most common component of staghorn calculi. However, a recent analysis of the composition of 52 staghorn calculi demonstrated that only 44% of stones were infection stones, while 56% of stones were metabolic, with calcium phosphate the most common (Viprakasit et al, 2011). Moreover, struvite-carbonate apatite was the most common stone composition among a population of African-American stone formers in Ohio, accounting for a third of stones in males and nearly half of stones in females in this population (Sarmina et al, 1987). **Because infection stones occur most commonly in those prone to frequent urinary tract infections, struvite stones occur more often in women than men by a ratio of 2:1 (Resnick, 1981).** Other populations at risk of recurrent infection include the elderly (Kohri et al, 1991), premature infants or infants born with congenital urinary tract malformation, diabetics, and those with urinary stasis as a result of urinary tract obstruction, urinary diversion, or neurologic disorders. Spinal cord-injured patients are at particular risk for both infection and metabolic stones owing to neurogenic urinary tract dysfunction and hypercalciuria related to immobility. Patients with a functionally complete cord transection are at highest risk of developing a staghorn calculus (DeVivo et al, 1984).

Miscellaneous Stones

Xanthine and Dihydroxyadenine Stones

Xanthine stones comprise a rare stone type that is often confused with uric acid stones because both are radiolucent. They form as a result of an inherited disorder in the catabolic enzyme xanthine dehydrogenase (XDH) or xanthine oxidase, which catalyzes the

conversion of xanthine to uric acid. Because xanthine is poorly soluble in urine, the high levels of xanthine that accumulate in XDH deficiency lead to xanthine stones (Cameron et al, 1993).

Allopurinol, which inhibits XDH and is consequently used to treat hyperuricemia and hyperuricosuria, can, at high levels, predispose to xanthine stones. This side effect is distinctly uncommon because the drug causes only partial inhibition of the enzyme and rarely reduces serum uric acid to levels lower than 3 mg/dL. Patients with Lesch-Nyhan syndrome who suffer from an inherited deficiency of the purine salvage enzyme HGPRT are occasionally treated with high enough doses of allopurinol to place them at risk for xanthine stones (Cameron et al, 1993).

Children with inherited deficiencies of adenine phosphoribosyltransferase can also present in infancy with renal complications and stones (Cameron et al, 1993). Children with adenine phosphoribosyltransferase deficiency may be difficult to distinguish from those with HGPRT deficiency because the insoluble product excreted, 2,8-dihydroxyadenine, is chemically similar to uric acid. Like xanthine stones, 2,8-dihydroxyadenine stones are extremely insoluble at any pH, but stone formation can be averted by the administration of allopurinol.

Ammonium Acid Urate Stones

Ammonium acid urate stones represent less than 1% of all stones (Herring, 1962; Kohn et al, 1986). In developing countries, however, endemic ammonium acid urate urolithiasis is still observed because it comprises bladder calculi in children (Minon Cifuentes and Pourmand, 1983; Vanwaeyenbergh et al, 1995). Conditions associated with ammonium acid urate crystallization include laxative abuse, recurrent urinary tract infection, recurrent uric acid stone formation, and inflammatory bowel disease (Dick et al, 1990; Pichette et al, 1997; Soble et al, 1999). Soble and

colleagues (1999) reviewed their experience with 44 patients identified as having stones composed of ammonium acid urate, although the ammonium acid urate contribution varied from 2% to 60%. Among these patients, 25% had a history of inflammatory bowel disease, 14% had a history of significant laxative abuse, 41% were morbidly obese, 36% had a history of recurrent urinary tract infections, and 21% had a history of recurrent uric acid stones. The subgroup of patients with inflammatory bowel disease and ileostomy as the sole clinical risk factor had the highest mean ammonium acid urate content (39%), and ammonium acid urate constituted the predominant stone type in seven of eight such patients.

Patients with ileostomy after colectomy have markedly reduced urinary volume, pH, and sodium and are not prone to hyperoxaluria as are other individuals with bowel disease because the colon is the main site of dietary oxalate absorption (Kennedy et al, 1982). Therefore these patients are prone to ammonium acid urate and uric acid stones rather than calcium oxalate stones. The underlying pathophysiologic mechanism of ammonium acid urate stone formation attributable to laxative abuse has been postulated to be dehydration resulting from gastrointestinal fluid loss, causing intracellular acidosis and enhanced ammonia excretion. Because urinary sodium is low in the setting of laxative use, urate complexes with abundant ammonia, thereby leading to urinary supersaturation of ammonium acid urate.

Bowyer and colleagues (1979) demonstrated that ammonium acid urate precipitation is favored at pH 6.2 to 6.3. The association of recurrent uric acid stones with ammonium acid urate stones is likely related to the shared risk factors of low urine volume and pH. Soble and colleagues (1999) identified nine patients with stones of mixed composition, containing both uric acid and ammonium acid urate (mean ammonium acid urate content 27%), although eight of the nine patients had uric acid as the predominant constituent (range 40% to 95%). They theorized that transient fluctuations in urinary acidity and ammonium and sodium levels may shift the balance between uric acid and sodium- or ammonium-bound urate excretion.

Among the ammonium acid urate stone producers in Soble and colleagues' (1999) study, obesity (BMI >30) was the most prevalent characteristic in 41% of patients, after excluding patients with inflammatory bowel disease and ileostomy (none of whom was obese). Indeed, a statistically significant correlation was found between BMI and ammonium acid urate content. This is consistent with recent evidence suggesting a correlation between stone risk and obesity (Powell et al, 2000) and between obesity and low urine pH (Maalouf et al, 2004b).

Matrix Stones

The association between urinary proteins and stone formation has long been recognized. Early experiments demonstrated that protein suspensions could promote calcium stone formation (Kimura et al, 1976). Both osteopontin and calprotectin have been shown to play a role in forming the matrix structure of urinary calcium stones (Tawada et al, 1999; Kleinman et al, 2004). However, stones composed predominantly of matrix are rare; these "stones" are typically radiolucent and may be mistaken for tumor or uric acid stones depending on the imaging study obtained (Bani-Hani et al, 2005).

The literature regarding matrix stones is sparse, consisting mostly of anecdotal case reports (Boyce and King, 1963; Allen and Spence, 1966; Bani-Hani et al, 2005). The matrix component of calcium-based stones comprises only 2.5% of the dry weight of the stone, whereas pure matrix stones may contain upwards of 65% protein (Allen and Spence, 1966). Boyce and Garvey (1956) determined that the composition of matrix stones was approximately two-thirds mucoprotein and one-third mucopolysaccharide by weight. Furthermore, they found that the matrix substance in crystalline calculi is closely related to the matrix substance found in matrix calculi. However, it is unclear why some matrix calculi fail to fully calcify.

Although some have theorized that reduced urinary calcium levels may account for the preferential formation of matrix stones (Boyce and King, 1959; Allen and Spence, 1966), a recent metabolic evaluation of five patients with matrix stones revealed normal urinary calcium excretion (Bani-Hani et al, 2005). In renal failure patients undergoing dialysis, proteinuria may contribute to an increased risk of matrix stone formation. In these patients, matrix stones have been shown to include both microfibrillar protein (Bommer et al, 1979) and β_2 -microglobulin (Linke et al, 1986). Recent analysis of the matrix stone from a single patient with *Proteus* urinary tract infection by scanning electron microscopy revealed fibrous netlike laminations containing bacterial, cellular, and crystalline material (Canales et al, 2009). Proteomic analysis identified 33 unique proteins, of which 90% had not been previously reported as components of matrix stones and 70% are considered inflammatory or defensive in nature.

Medication-Related Stones

Drug-induced stones form either directly as a result of precipitation and crystallization of a drug or its metabolite or indirectly by altering the urinary environment, making it favorable for metabolic stone formation (Daudon, 1999). Drugs such as loop diuretics (furosemide, bumetanide) and carbonic anhydrase inhibitors (acetazolamide, topiramate, and zonisamide) contribute to calcium stone formation (Matlaga et al, 2003). Ephedrine (Powell et al, 1998; Assimos et al, 1999), triamterene (Ettinger et al, 1980; Carr et al, 1990), guaifenesin (Assimos et al, 1999), silicate (Farrer and Rajfer, 1984), indinavir (Bruce et al, 1997; Gentle et al, 1997), and ciprofloxacin (Matlaga et al, 2003) have all been associated with stones composed of the drug itself in patients who consumed excessive amounts.

Medications That Directly Promote Stone Formation

Antiretroviral Agents. Indinavir sulfate is a protease inhibitor that has been shown to be effective in increasing CD4+ cell counts and decreasing HIV-RNA titers in patients infected with human immunodeficiency virus (HIV) or who have acquired immunodeficiency syndrome (Wu and Stoller, 2000). However, indinavir poses a risk for indinavir stone formation in treated patients, leading to an estimated incidence of 4% to 13% (Wu and Stoller, 2000). Indinavir is rapidly absorbed from the intestine, achieving peak plasma concentrations in less than 1 hour. The drug is metabolized in the liver and eliminated primarily in the stool, but about half of the ingested dose of indinavir is excreted essentially unchanged in the urine (Sutherland et al, 1997). In pure form, indinavir is relatively insoluble in aqueous solution, although the solubility is pH dependent. With a pK_a of 5.5, indinavir has a solubility of 0.300 mg/mL at pH 5, 0.035 mg/mL at pH 6.0, and 0.020 mg/mL at pH 7.0 (Daudon et al, 1997; Hermieu et al, 1999). Although indinavir solubility increases significantly at pH levels below 5.5, the standard dose of indinavir in an individual with an average urine volume and pH would produce a urinary concentration of indinavir near the limit of solubility 3 hours after ingestion (Daudon et al, 1997). As such, individuals taking indinavir on a regular basis are at high risk of producing indinavir stones because of the high urinary excretion and poor solubility of the drug at physiologic urinary pH. Initiation of indinavir in 54 asymptomatic, indinavir-naïve, HIV-positive individuals led to indinavir crystalluria in 67% of subjects (Gagnon et al, 2000). After the first 2 weeks, indinavir crystalluria remained constant at a frequency of approximately 25% of urine sediments examined at each test point.

Indinavir is now an infrequently used antiretroviral agent, replaced with newer generation agents. Kidney stone formation has been associated with a number of newer antiretroviral agents, including lopinavir-ritonavir (Doco-Lecompte et al, 2004), ritonavir-boosted atazanavir (Rockwood et al, 2011; Hamada et al, 2012), nelfinavir (Engeler et al, 2002), and amprenavir (Feicke et al, 2008). Ritonavir-boosted atazanavir, currently one of the more widely used agents, has been shown to have a nearly 7% incidence of stone formation, higher than most of the other new agents

(Rockwood et al, 2011; Hamada et al, 2012). Because stone formation associated with these agents is thought to be the result of high urinary excretion and low solubility of the drug in urine, agents with higher excretion rates are associated with higher rates of stone formation; 7% of ritonavir-boosted atazanavir is excreted in the urine unmetabolized versus less than 3% for nelfinavir and amprenavir, which have lower rates of stone formation.

Triamterene. Triamterene is a potassium-sparing diuretic commonly used for the treatment of hypertension. It is an uncommon stone composition, accounting for only 0.4% of 50,000 calculi in one report, with only one third of the stones composed largely or entirely of triamterene (Ettinger et al, 1980). An evaluation of triamterene stone formers revealed no significant differences between patients and matched control subjects with respect to total recovery of the drug, hourly excretion patterns, and urinary concentrations of triamterene and its sulfate metabolite (Ettinger, 1985). Approximately half of all subjects tested demonstrated urine concentrations of the sulfate metabolite that exceeded the observed solubility limit. One investigation determined that triamterene is more likely to become incorporated into existing stones or stone nuclei than to promote stone formation independently (Werness et al, 1982). This may account for the rarity of this stone in nonrecurrent stone formers, as well as the finding that hospitalization rates for urinary stones did not differ between patients prescribed triamterene and hydrochlorothiazide (Jick et al, 1982).

Guaifenesin and Ephedrine. Consumption of large quantities of guaifenesin and ephedrine can lead to stones composed of their metabolites (Powell et al, 1998; Assimios et al, 1999). Most of the patients reported to have these stones are found to have consumed large quantities of over-the-counter preparations of cold medicine for the stimulatory properties of the ephedrine component, and a history of drug abuse is not uncommon (Assimios et al, 1999). Herbal ecstasy and ma huang are also popular ephedrine-containing preparations that are abused for stimulatory properties (Mack, 1997). Unfortunately, chronic ephedrine use leads to tachyphylaxis and prompts the use of increasing doses to achieve a comparable effect. Serious toxicity may result from ephedrine abuse, including death, cardiomyopathy, stroke, hypertension, and seizures.

Silicate Stones. Silica is a common element seen in vegetables, whole grains, seafood, and even drinking water that is easily excreted in the urine (Matlaga et al, 2003). Silicate stones are extremely rare and have been associated with consumption of large amounts of silicate-containing antacids such as magnesium trisilicate (Haddad and Kouyoumdjian, 1986; Daudon, 1999).

Medications That Indirectly Promote Stone Formation. Other medications indirectly promote stone formation by increasing urinary stone risk factors. Corticosteroids, vitamin D, and phosphate-binding antacids can induce hypercalciuria. **Thiazides cause intracellular acidosis and subsequent hypocitraturia** (Nicar et al, 1984). Loop diuretics such as furosemide and bumetanide inhibit sodium and calcium resorption in the thick ascending loop of Henle, which in addition to a diuretic effect results in hypercalciuria (Matlaga et al, 2003). Renal calculi have been identified in up to 64% of low-birth-weight infants receiving furosemide therapy, and stones are consistently composed of calcium oxalate (Hufnagle et al, 1982; Shukla et al, 2001).

Carbonic anhydrase inhibitors such as acetazolamide block resorption of sodium bicarbonate at multiple segments in the nephron, thereby inducing a metabolic acidosis and leading to urinary alkalinization (Parfitt, 1969). Chronic use results in hypocitraturia, hypercalciuria, and increased risk for calcium phosphate stones (Matlaga et al, 2003). Topiramate is a widely used drug approved for the treatment of seizures and prophylaxis of migraine headaches but is additionally increasingly used for the treatment of a variety of other disorders, such as obesity, neuropathic pain, alcoholism, type 2 diabetes, cigarette smoking, and cocaine dependence. Topiramate inhibits several isoenzymes of carbonic anhydrase with subsequent stone-potentiating effects (Vega et al, 2007). Although the incidence of calcium stones with topiramate use in adults based on short-term clinical trials was reported

as 1.2% to 1.5% in the package insert, this number is thought to be an underestimate. Indeed, a recent retrospective study identified 150 individuals who were treated with topiramate out of 1500 adults in an electronic database from an epilepsy monitoring unit, among whom 75 were successfully contacted and queried regarding their kidney stone history (Maalouf et al, 2011). A total of eight subjects reported a diagnosis of kidney stones since the start of topiramate use, resulting in 10.7% prevalence. Furthermore, 15 patients among the 67 patients without a history of stones from the same study group were evaluated with computed tomographic imaging at an average of 43 months of topiramate use, revealing a 20% prevalence of asymptomatic stones, suggesting the problem is much more prevalent than previously suspected.

The risk of stone formation with topiramate use is related to its action as a carbonic anhydrase inhibitor. A recent cross-sectional study comparing 32 topiramate-treated patients with 50 normal controls revealed systemic metabolic acidosis, increased fractional excretion of bicarbonate, higher urine pH, and lower urinary citrate excretion in the topiramate-treated group (Welch et al, 2006). Likewise, in a short-term longitudinal study of seven patients before and 3 months after initiation of topiramate, significant metabolic acidosis and increased urine pH, bicarbonate excretion, and saturation of calcium phosphate were seen with initiation of the drug (Welch et al, 2006). Furthermore, topiramate-induced hypocitraturia demonstrates a dose-dependent response that additionally correlates inversely with duration of treatment (Kaplon et al, 2011). Zonisamide, a sulfonamide agent that also exerts an antiepileptic effect and has a weak carbonic anhydrase activity, has also been associated with increased risk of kidney stone formation (Zaccara et al, 2011).

Laxative abuse has also been associated with stone formation because persistent diarrhea increases the risk of ammonium acid urate stones. Patients abusing laxatives excrete large amounts of ammonia in the urine to eliminate excess acid, resulting in low urine pH. In the setting of low urine volume resulting from dehydration and low urinary sodium from laxative use, the urine of these patients can be highly supersaturated with respect to ammonium urate (Soble et al, 1999; Matlaga et al, 2003). Lastly, cytotoxic agents promote a high cell turnover, resulting in urinary excretion of large amounts of uric acid.

Anatomic Predisposition to Stones

Patients with anatomic anomalies associated with urinary obstruction and/or stasis have been noted to have a high incidence of associated stones. It has long been debated whether the predisposition to stone disease is a result of urinary stasis and delayed transit time through the nephron, leading to higher likelihood of crystal formation and retention, or if these patients form stones as a result of the same or unique metabolic abnormalities associated with stone formation.

Ureteropelvic Junction Obstruction

The incidence of renal calculi in patients with ureteropelvic junction obstruction (UPJO) is nearly 20% (David and Lavengood, 1975; Lowe and Marshall, 1984; Clark and Malek, 1987). However, Husmann and colleagues (1995) provided several lines of evidence to suggest that patients with UPJO and concurrent renal calculi carry the same metabolic risks as other stone formers in the general population. First, among 111 adult patients with UPJO and stones for whom long-term follow-up was available, 62% developed recurrent stones after treatment of the UPJO and 43% of the recurrences occurred in the contralateral kidney. These findings suggest that a metabolic predisposition persisted despite correction of the obstruction. Second, 76% of 42 patients with noninfectious stones who underwent a metabolic evaluation demonstrated an underlying metabolic abnormality that could account for the stones, a rate comparable to that of other stone formers (Pak, 1982; Yagisawa et al, 1999). Finally, the type and distribution of metabolic

abnormalities identified in these patients were similar to those of the general stone-forming population: hypercalciuria in 46% of patients, hyperuricosuria in 11%, hypocitraturia in 13%, primary hyperparathyroidism in 13%, and RTA in 3% (Pak et al, 1980). Treatment of patients with identifiable abnormalities significantly reduced their rate of recurrence, from 55% in patients managed conservatively to 17% in treated patients.

Matin and Stroom (2000) also performed metabolic evaluations before definitive repair in 47 patients with UPJO with or without associated stones. An identifiable abnormality was found in 67% of the stone patients compared with only 33% of the control group; urinary calcium and the incidence of hypercalciuria and hyperuricosuria were significantly higher in the patients with stones compared with the controls, further underscoring the contribution of pathophysiologic background to stone-forming risk in patients with anatomic abnormalities.

Similar findings in two series of children with UPJO and concurrent renal calculi further support a metabolic contribution to stone formation in the presence of renal obstruction. Tekin and colleagues (2001) prospectively compared children with UPJO with and without stones to a control group of calcium stone formers without UPJO. Both groups of stone formers, those with and without UPJO, exhibited significantly higher urinary levels of citrate and lower levels of oxalate compared with the non-stone-forming children with UPJO. Husmann and colleagues (1996) reported a 70-fold increased risk of stone formation in the pediatric population with UPJO compared with normal children. Among 22 children who underwent treatment of their stones and UPJO, 68% of patients with nonstruvite stones developed a recurrence after surgical treatment, and a metabolic abnormality was identified in 68%. Among the seven patients with nonstruvite renal calculi who did not experience a recurrence, only 29% had an identifiable metabolic abnormality. Thus correction of the UPJO did not prevent recurrent stones in most patients, further emphasizing the role of underlying metabolic abnormalities in the etiology of renal calculi in patients with UPJO.

Horseshoe Kidneys

Horseshoe kidneys occur with a prevalence of 0.25% but have an associated rate of renal calculi of 20% (Janetschek and Kunzel, 1988; Cussenot et al, 1992). Because of the high insertion of the ureter into the renal pelvis, there is a relative impairment of renal drainage, predisposing to UPJO. Therefore the risk of stone formation has been attributed to urinary stasis rather than to metabolic derangements. Raj and colleagues (2004) reviewed 37 patients with horseshoe kidneys and stones and identified at least one metabolic abnormality in all 11 patients in whom 24-hour urine collections were available. Compared with a group of stone formers with normal renal anatomy, the patients with horseshoe kidneys exhibited a similar distribution of metabolic derangements, with the exception that hypocitraturia was over-represented (55% in the patients with horseshoe kidneys vs. 31% in controls). It seems clear that although urinary stasis likely contributes to a propensity toward stone formation in patients with horseshoe kidneys, an underlying metabolic abnormality is required for stone formation to occur.

Caliceal Diverticula

Caliceal diverticula are associated with stones in up to 40% of patients (Middleton and Pfister, 1974). Like stones in horseshoe kidneys, it is unclear whether the stones are caused by local anatomic obstruction and urinary stasis or are due to underlying metabolic factors. Two groups of investigators have addressed this issue. Hsu and Stroom (1998) identified metabolic abnormalities, including hypercalciuria, hyperoxaluria, and hyperuricosuria, in 50% of 14 patients with stone-bearing caliceal diverticula. Notably, 64% of patients reported a history of synchronous or metachronous stones at a site distinct from the diverticulum, supporting the idea of underlying metabolic risk as a contributing cause of the stones. In

contrast, Liatsikos and colleagues (2000) compared 49 patients with caliceal diverticula and stones with 44 stone formers without diverticula and found a low rate of metabolic abnormalities in both groups (25% in patients with diverticula and 23% in the control patients). Of note, however, the metabolic evaluation in this study involved measurement of only urinary volume, creatinine, calcium, phosphorus, oxalate, and uric acid. Because low urinary pH and hypocitraturia are identified in approximately 10% and 28% of recurrent stone formers, respectively (Levy et al, 1995), the number of metabolic abnormalities reported in this series is likely under-represented. Finally, a study by Matlaga and colleagues (2007) evaluated 29 patients who underwent percutaneous treatment of stone-bearing calyceal diverticuli and compared their 24-hour urine collections with those of 245 calcium oxalate stone formers and 162 normal controls. The urinary stone risk parameters of the patients with calyceal diverticular stones were similar to those of calcium oxalate stone formers, who demonstrated significantly greater hypercalciuria and higher calcium oxalate supersaturation compared with normal controls. Interestingly, urine aspirated directly from the diverticulum had lower calcium oxalate supersaturation than that of urine obtained from the ipsilateral and contralateral renal pelvis. These findings imply that calyceal diverticular calculi arise from a combination of metabolic abnormalities and urinary stasis.

Stones formed in caliceal diverticula are mainly composed of calcium oxalate monohydrate, but they can also contain struvite-carbonate apatite owing to an infectious component. Concomitant urinary tract infection is found in up to 40% of cases, with *E. coli*, *Proteus*, and *Pseudomonas* being the most frequent pathogens (Monreal et al, 1998; Daudon et al, 2003).

Medullary Sponge Kidney

Medullary sponge kidney (MSK) is a disorder characterized by ectasia of the renal collecting ducts. Nephrocalcinosis and renal calculi are frequent complications of MSK (Lavan et al, 1971; Parks et al, 1982; Sage et al, 1982; Ginalska et al, 1990), but the exact risk factors for stone formation are not clearly understood. Although recurrent infection and urinary stasis within the ectatic tubules pose a risk for stone formation (Ginalska et al, 1990), renal tubular defects, including hypercalciuria, impaired renal concentrating ability, and defective urinary acidification after an ammonium chloride load, have been detected in some MSK patients (Granberg et al, 1971), further potentiating the risk of stone formation. Osther and colleagues (1988) performed ammonium chloride load tests in 13 patients with MSK and found renal acidification defects in 9 patients: 8 with distal RTA and 1 with proximal RTA. Likewise, Higashihara and colleagues (1984) reported renal acidification defects in 80% of 11 MSK patients (36% with distal RTA) and impaired concentrating ability in 90% of these 11 patients. The identification of mutations in the hydrogen proton pump genes *ATP6V1B1* and *ATP6V0A4* in two patients with MSK lends further support to an association between MSK and distal RTA (Carboni et al, 2009).

Despite these findings, three studies performed specifically on MSK patients with nephrolithiasis revealed no case of associated RTA (O'Neill et al, 1981; Parks et al, 1982; Yagisawa et al, 2001). O'Neill and colleagues (1981) identified hypercalciuria as the most common metabolic abnormality in 17 patients with MSK and nephrolithiasis, occurring in 88% of patients and attributed to absorptive hypercalciuria in most cases (59%). The spectrum of abnormalities in these patients was judged to be comparable with that of the general stone-forming population. Other investigators identified hypercalciuria less frequently, in only 9% to 44% of MSK patients with nephrolithiasis. In some cases, the cause of the hypercalciuria was attributed to renal calcium leak by which renal calcium reabsorption was presumed to be impaired by damaged renal tubules (Yendt, 1981; Parks et al, 1982; Yagisawa et al, 2001). Yagisawa and coworkers (2001) identified hypocitraturia as the most common metabolic abnormality, occurring in 77% of 22 MSK patients. Kinoshita (1990) likewise reported hypocitraturia in

58% of MSK patients. Thus it appears that although renal acidification defects may be associated with MSK, hypercalciuria and hypocitraturia are likely contributing factors even in the absence of RTA.

Stones in Pregnancy

Symptomatic stones during pregnancy occur at a rate of 1 in 250 (Lewis et al, 2003) to 1 in 3000 (Butler et al, 2000) pregnant women. Like stones in nonpregnant women, they occur more commonly in white than African-American women (Lewis et al, 2003). The majority of symptomatic stones occur in the second and third trimesters of pregnancy, heralded by symptoms of flank pain or hematuria (Stothers and Lee, 1992; Butler et al, 2000; Biyani and Joyce, 2002; Lewis et al, 2003). The diagnosis can be difficult in this patient population; up to 28% of women are misdiagnosed with appendicitis, diverticulitis, or placental abruption (Stothers and Lee, 1992).

A number of physiologic changes occur during pregnancy. Physiologic hydronephrosis occurs in up to 90% of pregnant women and persists up to 4 to 6 weeks postpartum (Swanson et al, 1995). Although hydronephrosis may be in part due to the effects of progesterone, compression of the ureters by the gravid uterus is at least a contributory, if not the primary, factor (Gorton and Whitfield, 1997; McAleer and Loughlin, 2004). Dilation is typically greater in the right ureter as a result of the engorged uterine vein and derotation of the enlarged uterus (Biyani and Joyce, 2002). The physiologic dilation may promote crystallization as a result of urinary stasis (Swanson et al, 1995), and the increased renal pelvic pressure has been suggested to increase the likelihood of stone movement and symptoms.

Important physiologic changes in the kidney occur during pregnancy and modulate urinary stone risk factors. Renal blood flow increases, leading to a 30% to 50% rise in glomerular filtration rate, which subsequently increases the filtered loads of calcium, sodium, and uric acid (McAleer and Loughlin, 2004). Hypercalciuria is further enhanced by placental production of $1,25(\text{OH})_2\text{D}_3$, which increases intestinal calcium absorption and secondarily suppresses PTH (Gertner et al, 1986; Biyani and Joyce, 2002). Hyperuricosuria has also been reported as a result of increased filtered load of uric acid (Swanson et al, 1995).

Despite increases in a number of stone-inducing analytes, pregnant women have been shown to excrete increased amounts of inhibitors such as citrate, magnesium, and glycoproteins (Mairkranz et al, 1987; Smith et al, 2001). Therefore the overall risk of stone formation has been reported to be similar in gravid and non-gravid women (Coe et al, 1978; Drago et al, 1982). Although some studies found that the stone composition is similar between gravid and nongravid women, one multi-institutional study found that 74% of stones from pregnant women were composed predominantly of calcium phosphate and 26% were predominantly calcium oxalate (Coe et al, 1978; Drago et al, 1982; Ross et al, 2008).

KEY POINTS: PATHOGENESIS

- Absorptive hypercalciuria is characterized by normal serum calcium, normal or suppressed PTH, normal fasting urinary calcium, and elevated urinary calcium.
- Renal hypercalciuria is due to impaired renal calcium reabsorption, which stimulates PTH secretion and leads to fasting hypercalciuria.
- Resorptive hypercalciuria is primarily due to primary hyperparathyroidism but may be seen with granulomatous diseases that elaborate $1,25(\text{OH})_2\text{D}_3$.
- The most important determinant of uric acid stone formation is low urinary pH.
- Low urine pH seen in uric acid stone formers is likely due to impaired ammoniogenesis as a result of insulin resistance and excess acid production.
- In distal RTA, a defective H^+ -ATPase accounts for excretion of excess acid into the distal tubule.
- Formation of infection stones requires alkaline urine that can be achieved only with infection with urease-producing bacteria.
